We dedicate this edition to all those who advocate to improve the health, enrich the development, and promote the well-being of children and youth throughout the world. Their efforts are essential to achieving these goals and sustaining our hope for a better future.

Preface

The publication of this 17th Edition of *Nelson Textbook of Pediatrics* provides a new and comprehensive update and synthesis of pediatric medicine and related science. It continues to represent the "state of the art" on the broad spectrum of normal and abnormal growth and development and of disorders and diseases that affect children and youth.

This is a time of great opportunity. The promise of medicine, biologic sciences, and technology is greater than ever before. Knowledge of human development, behavior, and disease from molecular to sociologic levels is increasing exponentially. This has led to greater understanding of health and illness in children and youth and substantial improvements in the quality of their care. These advances also hold promise of effectively addressing the new and re-emerging diseases threatening children and their families.

Unfortunately, many children worldwide have not yet benefited from the significant advances in the prevention and treatment of health problems, primarily because of a lack of political will and misplaced priorities. Poverty, war, and bioterrorism present additional substantial risks. In order for our increasing knowledge to benefit all children and youth, good medicine needs to be coupled with effective advocacy.

This edition provides the knowledge that practitioners, house staff, medical students, and others involved in pediatric medicine need to address the enormous range of biopsychosocial problems that children and youth may face. As in previous editions, our goal is to be comprehensive, concise, and reader friendly within a single volume, embracing both the science and the art of pediatrics in our presentation.

The 17th Edition represents a substantial revision and reorganization of the textbook based on a complete review of the field of pediatrics. There are many new chapters and substantial expansion or significant modification of others. Every subject has been scrutinized for possible improvement in its exposition, and no chapter has been left unimproved. Although to an ill child and his or her family and physician even the rarest disorder is of central importance, all health problems cannot be covered with the same degree of detail in one general textbook of pediatrics. Thus, leading articles and subspecialty texts are referenced and should be consulted when more information is desired.

The value of this textbook is due to its expert contributors, and we are indebted to ours for their hard work, knowledge, thoughtfulness, and good judgment. Our sincere appreciation also goes to Judy Fletcher, Deborah Thorp, and Robin Davis at Elsevier and to Carolyn Redman at the Pediatric Department of the Medical College of Wisconsin. All of us have worked hard to produce an edition that will be helpful to those who provide care for children and youth and to those desiring to know more about children's health worldwide.

In this edition we have had informal assistance from many faculty and house staff of the departments of pediatrics at Stanford University, the Medical College of Wisconsin, and Eastern Virginia Medical School. The help of these individuals and of the many practicing pediatricians from around the world who have taken the time to offer thoughtful suggestions is greatly appreciated.

Last and certainly not least, we especially wish to thank our wives for their patience and understanding without which this textbook would not have been possible.

Richard E. Behrman MD
Robert M. Kliegman MD
Hal B. Jenson MD

Contributors

Jon S. Abramson MD

Professor and Chair,
Department of Pediatrics,
Wake Forest, University School of Medicine;
North Carolina Baptist Hospital,
Winston-Salem, North Carolina
Streptococcus pneumoniae (Pneumococcus)

Mark J. Abzug MD

Professor of Pediatrics (Pediatric Infectious Diseases),
University of Colorado, School of Medicine;
The Children's Hospital,
Denver, Colorado
Nonpolio Enteroviruses

William G. Adams MD

Assistant Professor of Pediatrics,
Boston University School of Medicine,
Boston, Massachusetts
Rabies

John J. Aiken MD

Assistant Professor of Pediatric Surgery,
Medical College of Wisconsin,
Milwaukee, Wisconson
Inguinal Hernias

Hassan H. A-Kader MD

Associate Professor of Pediatrics,
University of Arizona,
Tucson, Arizona
Cholestasis

Ramin Alemzadeh MD

Associate Professor of Pediatrics,
Section of Endocrinology and Diabetes,
Medical College of Wisconsin;
Director,
Diabetes Program,
Children's Hospital of Wisconsin,
Milwaukee, Wisconsin
Diabetes Mellitus in Children

Alia Y. Antoon MD

Assistant Clinical Professor,
Harvard Medical School;
Chief of Pediatrics,
Shriners Burns Hospital;
Pediatrician,
Massachusetts General Hospital,
Boston, Massachusetts
Burn Injuries;
Cold Injuries

Carola A. S. Arndt MD

Associate Professor,
Mayo Medical School;
Department of Pediatrics,
Division of Pediatric Hematology-Oncology,
Mayo Clinic and Foundation,
Rochester, Minnesota
Soft Tissue Sarcomas;
Neoplasms of Bone

Stephen S. Arnon MD

Senior Investigator and Chief,
Infant Botulism Treatment and Prevention Program,
California Department of Health Services,
Berkeley, California
Botulism (*Clostridium botulinum*);
Tetanus (*Clostridium tetani*)

Stephen C. Aronoff MD

Professor and Chair,
Department of Pediatrics,
Temple University School of Medicine,
Philadelphia, Pennsylvania
Candida;
Cryptococcus neoformans;
Aspergillus;
Histoplasmosis (*Histoplasma capsulatum*);
Blastomycosis (*Blastomyces dermatitidis*);
Paracoccidioides brasiliensis;
Sporotrichosis (*Sporothrix schenckii*);
Zygomycosis;
Primary Amebic Meningoencephalitis;
Nonbacterial Food Poisoning

David M. Asher MD

Chief,
Laboratory of Bacterial, Parasitic, and Unconventional Agents,
Division of Emerging and Transfusion-Transmitted Diseases,
Office of Blood Research and Review,
Center for Biologics Evaluation and Research,
U.S. Food and Drug Administration,
Kensington, Maryland
Transmissible Spongiform Encephalopathies

Joann L. Ater MD

Associate Professor of Pediatrics,
University of Texas
M. D. Anderson Cancer Center,
Houston, Texas
Brain Tumors in Childhood;
Neuroblastoma

Dan Atkins MD

Associate Professor of Pediatrics,
University of Colorado,
Health Sciences Center;
Director,
Ambulatory Pediatrics,
National Jewish Medical Research Center,
Denver, Colorado
Diagnosis of Allergic Disease;
Principles of Treatment of Allergic Disease

Marilyn Augustyn MD

Assistant Professor,
Boston University School of Medicine;
Boston Medical Center,
Boston, Massachusetts
Impact of Violence on Children

Ellis D. Avner MD

The Gertrude Lee Chandler Tucker Professor and Chair,
Department of Pediatrics,
Case Western Reserve University School of Medicine;
Chief Medical Officer,
Rainbow Babies and Children's Hospital,
University Hospitals of Cleveland,
Cleveland, Ohio

Collin S. Goto MD

Assistant Clinical Professor of Pediatrics,
University of California, San Diego;
Attending Physician,
Division of Emergency Medicine and Toxicology,
Children's Hospital and Health Center,
The California Poison Control System,
San Diego, California
Heavy Metal Intoxication

David Gozal MD

Children's Foundation Chair for Pediatric Research,
Professor of Pediatrics, Pharmacology, and Toxicology,
University of Louisville;
Director,
Division of Sleep Medicine,
Kosair Children's Hospital,
Louisville, Kentucky
Neuromuscular Diseases with Pulmonary Consequences

Michael Green MD, MPH

Professor of Pediatrics and Surgery,
University of Pittsburgh School of Medicine;
Children's Hospital of Pittsburgh,
Pittsburgh, Pennsylvania
Infections in Immunocompromised Persons

Thomas P. Green MD

Chair,
Department of Pediatrics,
Women's Board Centennial Professor,
Feinberg School of Medicine,
Northwestern University;
Physician-in-Chief,
Children's Memorial Hospital,
Chicago, Illinois
Disorders of the Lungs and Lower Airways;
Congenital Disorders of the Lungs, Pulmonary Edema;
Pulmonary Hemorrhage, Embolism, and Infection

Larry A. Greenbaum MD, PhD

Associate Professor of Pediatrics,
Medical College of Wisconsin;
Attending Physician,
Children's Hospital of Wisconsin,
Milwaukee, Wisconsin
Pathophysiology of Body Fluids and Fluid Therapy

David Grossman MD, MPH

Professor of Pediatrics,
University of Washington;
Director,
Harborview Injury Prevention and Research Center,
Seattle, Washington
Injury Control

Linda Sayler Gudas PhD

Assistant Clinical Professor,
Harvard Medical School;
Assistant in Psychiatry,
Department of Psychology,
Children's Hospital,
Boston, Massachusetts
Grief and Bereavement

James G. Gurney PhD

Associate Professor of Pediatrics,
Division of Epidemiology and Clinical Research,
University of Minnesota,
Minneapolis, Minnesota
Epidemiology of Childhood and Adolescent Cancer

Gabriel G. Haddad MD

Professor of Pediatrics and Neuroscience,
University Chair,
Department of Pediatrics,
Albert Einstein College of Medicine;
Pediatrician-in-Chief,
Children's Hospital at Montefiore,
Bronx, New York
Development of the Respiratory System;
Regulation of Respiration;
Respiratory Pathophysiology;
Defense Mechanisms and Metabolic Functions of the Lung;
Diagnostic Approach to Respiratory Disease;
Obstructive Sleep Apnea and Hypoventilation;

Primary Ciliary Dyskinesia (Immotile Cilia Syndrome)

Joseph Haddad Jr. MD

Associate Professor and Vice Chair,
Department of Otolaryngology/Head and Neck Surgery,
Columbia University College of Physicians and Surgeons;
Lawrence Savetsky Chair and Director,
Pediatric Otolaryngology,
Children's Hospital of New York-Presbyterian,
New York, New York
Congenital Disorders of the Nose;
Acquired Disorders of the Nose;
Nasal Polyps;
Clinical Manifestations;
Hearing Loss;
Congenital Malformations;
Diseases of the External Ear;
The Inner Ear and Diseases of the Bony Labyrinth;
Traumatic Injuries of the Ear and Temporal Bone;
Tumors of the Ear and Temporal Bone

Judith G. Hall MD

Professor of Pediatrics and Medical Genetics,
University of British Columbia;
British Columbia's Children's Hospital,
Vancouver, British Columbia, Canada
Chromosomal Clinical Abnormalities;
Genetic Counseling

Scott B. Halstead MD

Adjunct Professor of Preventive Medicine and Biometrics,
Uniformed Services University of the Health Sciences,
Bethesda, Maryland
Arboviral Encephalitis in North America;
Arboviral Encephalitis Outside North America;
Dengue Fever and Dengue Hemorrhagic Fever;
Yellow Fever;
Other Viral Hemorrhagic Fevers;
Hantaviruses

Margaret R. Hammerschlag MD

Professor of Pediatrics and Medicine,
Director,
Division of Pediatric Infectious Diseases,
SUNY Downstate Medical Center,
Brooklyn, New York
Chlamydial Infections

Aaron Hamvas MD

Professor of Pediatrics,
Washington University School of Medicine;
Medical Director,
Neonatal Intensive Care Unit,
St. Louis Children's Hospital,
St. Louis, Missouri
Pulmonary Alveolar Proteinosis;
Inherited Disorders of Surfactant Protein Metabolism

James C. Harris MD

Professor of Psychiatry and Behavioral Sciences,
Professor of Pediatrics,
The Johns Hopkins University,
School of Medicine;
Director,
Developmental Neuro-Psychiatry,
Johns Hopkins University Hospital,
Baltimore, Maryland
Disorders of Purine and Pyrimidine Metabolism

Gary E. Hartman MD

Professor of Surgery and Pediatrics,
George Washington University School of Medicine;
Chief,
Pediatric Surgery,
Children's National Medical Center,
Washington, DC
Acute Appendicitis;
Diaphragmatic Hernia;
Epigastric Hernia

David B. Haslam MD

Assistant Professor of Pediatrics and Molecular Microbiology,
Washington University School of Medicine;
St. Louis Children's Hospital,
St. Louis, Missouri
Enterococcus

Robert H. A. Haslam MD

Emeritus Professor and Chair,
Department of Pediatrics,
Professor of Medicine (Neurology),

University of Toronto;
Emeritus Pediatrician-in-Chief and Staff Neurologist,
Hospital for Sick Children,
Toronto, Ontario, Canada
Neurologic Evaluation;
Headaches;
Neurocutaneous Syndromes;
Brain Abscess;
Pseudotumor Cerebri;
Spinal Cord Disorders

Fern R. Hauck MD

Associate Professor and Director of Research,
Department of Family Medicine,
University of Virginia Health System,
Charlottesville, Virginia
Sudden Infant Death Syndrome

Paul R. Haut MD

Associate Professor of Pediatrics,
Indiana University School of Medicine;
Director of Pediatric Stem Cell Transplantation,
James Whitcomb Riley Hospital for Children,
Indianapolis, Indiana
Pulmonary Tumors

Gregory F. Hayden MD

Professor of Pediatrics,
Director,
Center for the Advancement of Generalist Medicine,
University of Virginia School of Medicine,
Charlottesville, Virginia
The Common Cold;
Acute Pharyngitis

Jacqueline T. Hecht PhD

Professor of Pediatrics,
Director,
Genetic Counseling Program,
University of Texas-Houston,
Houston, Texas
General Considerations;
Disorders Involving Cartilage Matrix Proteins;
Disorders Involving Transmembrane Receptors;
Disorders Involving Ion Transporter;
Disorders Involving Transcription Factors;
Disorders Involving Defective Bone Resorption;
Disorders for Which Defects Are Poorly Understood or Unknown

William C. Heird MD

Professor of Pediatrics,
Baylor College of Medicine;
Children's Nutrition Research Center,
Houston, Texas
Nutritional Requirements;
The Feeding of Infants and Children;
Food Insecurity, Hunger, and Undernutrition;
Vitamin Deficiencies and Excesses

J. Owen Hendley MD

Professor of Pediatrics,
University of Virginia School of Medicine,
Charlottesville, Virginia
Sinusitis;
Retropharyngeal Abscess, Lateral Pharyngeal (Parapharyngeal) Abscess, and Peritonsillar Cellulitis/Abscess

Fred M. Henretig MD

Professor of Pediatrics and Emergency Medicine,
University of Pennsylvania School of Medicine;
Director,
Section of Clinical Toxicology,
Children's Hospital of Philadelphia,
Philadelphia, Pennsylvania
Biologic and Chemical Terrorism

Gloria P. Heresi MD

Associate Professor of Pediatric Infectious Diseases,
University of Texas-Houston Health Science Center;
Memorial Hermann Children's Hospital,
Houston, Texas
Cholera (*Vibrio cholerae*);
Campylobacter;
Yersinia;
Aeromonas and *Plesiomonas*

Albert C. Hergenroeder MD

Professor of Pediatrics,

Baylor College of Medicine;
Chief,
Adolescent Medicine Service and Sports Medicine Clinic,
Texas Children's Hospital,
Houston, Texas
Sports Medicine

Cynthia E. Herzog MD

Associate Professor,
University of Texas M. D. Anderson Cancer Center,
Houston, Texas
Retinoblastoma;
Gonadal and Germ Cell Neoplasms;
Neoplasms of the Liver;
Benign Vascular Tumors;
Rare Tumors

Lauren D. Holinger MD

Professor of Otolaryngology/Head and Neck Surgery,
Northwestern University;
Paul H. Holinger, MD,
Professor, Head,
Division of Pediatric Otolaryngology and Department of Communicative Disorders,
Children's Memorial Hospital,
Chicago, Illinois
Congenital Anomalies of the Larynx;
Foreign Bodies of the Airway;
Laryngotracheal Stenosis, Subglottic Stenosis;
Congenital Anomalies of the Trachea and Bronchi;
Neoplasms of the Larynx, Trachea, and Bronchi

Steve Holve MD

Clinical Professor of Pediatrics,
The Johns Hopkins University School of Medicine,
Baltimore, Maryland;
Chief,
Department of Pediatrics,
Tuba City Indian Medical Center,
Tuba City, Arizona
Envenomations

Jeffrey D. Hord MD

Associate Professor of Pediatrics,
Northwestern Ohio Universities College of Medicine;
Director,
Pediatric Hematology/Oncology,
Children's Hospital Medical Center,
Akron, Ohio
The Acquired Pancytopenias

William A. Horton MD

Professor of Molecular and Medical Genetics,
Oregon Health Sciences University;
Director of Research,
Shriners Hospital for Children,
Portland, Oregon
General Considerations;
Disorders Involving Cartilage Matrix Proteins;
Disorders Involving Transmembrane Receptors;
Disorders Involving Ion Transporter;
Disorders Involving Transcription Factors;
Disorders Involving Defective Bone Resorption;
Disorders for Which Defects Are Poorly Understood or Unknown

Peter Hotez MD, PhD

Professor and Chair,
Department of Microbiology and Tropical Medicine,
The George Washington University Medical Center,
Washington, DC
Hookworms (*Ancylostoma* and *Necator americanus*)

Michelle S. Howenstine MD

Associate Professor of Clinical Pediatrics,
Indiana University School of Medicine;
James Whitcomb Riley Hospital for Children,
Indianapolis, Indiana
Interstitial Lung Diseases

E. Eugene Hoyme MD

Professor and Chief,
Division of Medical Genetics,
Department of Pediatrics,
Stanford University School of Medicine;
Chief,
Genetics Service,
Lucile Salter Packard Children's Hospital,
Stanford, California
The Molecular Basis of Genetic Disorders;
Molecular Diagnosis of Genetic Diseases;
Patterns of Inheritance

Vicki Huff PhD

Associate Professor of Molecular Genetics/Cancer Genetics,
University of Texas M.D. Anderson Cancer Center,
Houston, Texas
Neoplasms of the Kidney

Walter T. Hughes MD

Professor of Pediatrics,
University of Tennessee College of Medicine;
Emeritus Member,
Department of Infectious Diseases,
St. Jude Children's Research Hospital,
Memphis, Tennessee
Pneumocystis carinii

Carl E. Hunt MD

Adjunct Professor of Pediatrics,
Uniformed Services University of the Health Sciences;
Director,
National Center on Sleep Disorders Research,
National Heart, Lung, and Blood Institute,
National Institutes of Health,
Bethesda, Maryland
Sudden Infant Death Syndrome

Sunny Zaheed Hussain MD

Fellow in Pediatric Gastroenterology,
University of Pittsburgh School of Medicine;
Children's Hospital of Pittsburgh,
Pittsburgh, Pennsylvania
The Esophagus

Jeffrey Hyams MD

Professor of Pediatrics,
University of Connecticut School of Medicine;
Head,
Division of Digestive Diseases and Nutrition,
Connecticut Children's Medical Center,
Hartford, Connecticut
Inflammatory Bowel Disease;
Food Allergy (Food Hypersensitivity);
Eosinophilic Gastroenteritis;
Malformations;
Ascites;
Peritonitis

Richard F. Jacobs MD

Horace C. Cabe Professor of Pediatrics,
University of Arkansas for Medical Sciences;
Chief,
Pediatric Infectious Diseases,
Arkansas Children's Hospital,
Little Rock, Arkansas
Actinomyces;
Nocardia;
Tularemia (*Francisella tularensis*);
Brucella

Norman Jaffe MD

Professor of Pediatrics,
University of Texas M. D. Anderson Cancer Center,
Houston, Texas
Neoplasms of the Kidney

Renée R. Jenkins MD

Professor and Chair of Pediatrics,
Howard University College of Medicine;
Chair,
Department of Pediatrics and Child Health,
Howard University Hospital,
Washington, DC
The Epidemiology of Adolescent Health Problems;
Delivery of Health Care to Adolescents;
Depression;
Suicide;
Violent Behavior;
Substance Abuse;
The Breast;
Menstrual Problems;
Contraception;
Pregnancy;
Sexually Transmitted Diseases

Hal B. Jenson MD

Professor and Chair,
Department of Pediatrics,
Director,
Center for Pediatric Research,
Eastern Virginia Medical School
and Children's Hospital of The King's Daughters;

Senior Vice President for Academic Affairs,
Children's Hospital of The King's Daughters,
Norfolk, Virginia
Chronic Fatigue Syndrome;
Epstein-Barr Virus;
Lymphocytic Choriomeningitis Virus;
Polyomaviruses;
Human T-Cell Lymphotropic Viruses Types I and II

Chandy C. John MD

Assistant Professor of Pediatrics,
Case Western Reserve University School of Medicine;
Division of Pediatric Infectious Diseases,
Co-Director,
Rainbow Center for International Child Health,
Rainbow Babies and Children's Hospital,
Cleveland, Ohio
Amebiasis;
Trichomoniasis (*Trichomonas vaginalis*);
Health Advice for Children Traveling Internationally

Charles F. Johnson MD

Professor of Pediatrics,
The Ohio State University; Children's Hospital,
Columbus, Ohio
Abuse and Neglect of Children

Michael V. Johnston MD

Professor of Neurology and Pediatrics,
Kennedy Krieger Institute
and The Johns Hopkins University School of Medicine,
Baltimore, Maryland
Congenital Anomalies of the Central Nervous System;
Seizures in Childhood;
Conditions that Mimic Seizures;
Movement Disorders;
Encephalopathies;
Neurodegenerative Disorders of Childhood;
Acute Stroke Syndromes

Richard B. Johnston Jr. MD

Professor of Pediatrics,
University of Colorado School of Medicine;
National Jewish Medical and Research Center,
Denver, Colorado
Monocytes and Macrophages;
The Complement System

Kenneth Lyons Jones MD

Professor of Pediatrics,
University of California, San Diego,
School of Medicine;
UCSD Medical Center,
San Diego, California
Dysmorphology

Harry J. Kallas MD

Associate Professor of Pediatric Critical Care Medicine,
Pediatric Medical Director,
Life Flight,
University of California, Davis,
School of Medicine;
UC Davis Children's Hospital,
Sacramento, California
Drowning and Near-Drowning

Lewis J. Kass MD

Assistant Professor of Pediatrics,
Albert Einstein College of Medicine;
Children's Hospital at Montefiore,
Bronx, New York
Obstructive Sleep Apnea and Hypoventilation

Mark A. Kay MD, PhD

Departments of Pediatrics and Genetics,
Stanford University,
Stanford, California
Gene Therapy

Allesandra N. Kazura MD

Assistant Professor of Psychiatry and Human Behavior,
Brown University School of Medicine;
Brown University Centers for Behavioral and Preventive Medicine,
Providence, Rhode Island
Psychosomatic Illness

James W. Kazura MD

Professor of Medicine,
International Health, and Pathology,
Case Western Reserve University School of Medicine;

Attending Physician,
University Hospitals of Cleveland,
Cleveland, Ohio
Ascariasis (*Ascaris lumbricoides*);
Trichuriasis (*Trichuris trichiura*);
Enterobiasis (*Enterobius vermicularis*);
Strongyloidiasis (*Strongyloides stercoralis*);
Lymphatic Filariasis (*Brugia malayi, Brugia timori,* and *Wuchereria bancrofti*);
Other Tissue Nematodes;
Toxocariasis (Visceral and Ocular Larva Migrans);
Trichinosis (*Trichinella spiralis*)

Desmond P. Kelly MD

Clinical Associate Professor of Pediatrics,
University of North Carolina School of Medicine;
Director,
Clinical Programs,
All Kinds of Minds,
Chapel Hill, North Carolina
Patterns of Development and Function

Kathi J. Kemper MD, MPH

Professor of Pediatrics,
Wake Forest University School of Medicine;
Brenner Children's Hospital
Herbal Medicines

John A. Kerner MD

Professor of Pediatrics,
Director of Nutrition,
Director of Pediatric Gastroenterology and Nutrition Fellowship,
Stanford University School of Medicine;
Director,
Nutrition Support Team,
Medical Director,
Children's Home Pharmacy,
Lucile Salter Packard Children's Hospital,
Palo Alto, California
Malabsorptive Disorders

Seema Khan MD

Assistant Professor of Pediatric Gastroenterology,
University of Pittsburgh School of Medicine;
Children's Hospital of Pittsburgh,
Pittsburgh, Pennsylvania
The Esophagus

Charles H. King MD

Associate Professor of Medicine and International Health,
Case Western Reserve School of Medicine;
Attending Physician,
University Hospitals of Cleveland,
Cleveland, Ohio
Schistosomiasis (*Schistosoma*);
Flukes (Liver, Lung, and Intestinal)

Stephen Kinsman MD

Assistant Professor of Pediatrics and Neurology,
Director of Pediatric Neurology,
University of Maryland School of Medicine,
Baltimore, Maryland
Congenital Anomalies of the Central Nervous System

Bruce L. Klein MD

Associate Professor of Pediatrics and Emergency Medicine,
The George Washington University School of Medicine and Health Sciences;
Medical Director,
Pediatric Transport Service,
Children's National Medical Center,
Washington, DC
Acute Care of the Multiple Trauma Victim

Marisa S. Klein-Gitelman MD, MPH

Assistant Professor of Pediatrics,
Feinberg School of Medicine,
Northwestern University;
Interim Head,
Division of Immunology/Rheumatology,
Children's Memorial Hospital,
Chicago, Illinois
Systemic Lupus Erythematosus

Robert M. Kliegman MD

Professor and Chair,
Department of Pediatrics,
Medical College of Wisconsin;
Pediatrician in Chief,
Pam and Les Muma Chair in Pediatrics,

Children's Hospital of Wisconsin,
Milwaukee, Wisconsin
  Mucopolysaccharidoses;
  Overview of Mortality and Morbidity;
  The Newborn Infant;
  High-Risk Pregnancies;
  The Fetus;
  The High-Risk Infant;
  Clinical Manifestations of Diseases in the Newborn Period;
  Nervous System Disorders;
  Delivery Room Emergencies;
  Respiratory Tract Disorders;
  Digestive System Disorders;
  Blood Disorders;
  Genitourinary System;
  The Umbilicus;
  Metabolic Disturbances;
  The Endocrine System

William C. Koch MD

Associate Professor of Pediatrics,
Virginia Commonwealth University;
Division of Infectious Diseases,
Medical College of Virginia,
Richmond, Virginia
  Parvovirus B19

Steve Kohl MD

Clinical Professor of Pediatrics,
Oregon Health and Sciences University,
Portland, Oregon
  Herpes Simplex Virus

Gerald P. Koocher PhD

Dean,
Graduate School for Health Studies,
Simmons College,
Boston, Massachusetts
  Grief and Bereavement

Jill E. Korbin PhD (Anthropology)

Professor of Anthropology,
Associate Dean,
College of Arts and Sciences,
Case Western Reserve University;
Co-Director,
Schubert Center for Child Development,
Cleveland, Ohio
  Cultural Issues in Pediatric Care

Peter J. Krause MD

Professor of Pediatrics,
University of Connecticut School of Medicine;
Director,
Infectious Diseases,
Connecticut Children's Medical Center,
Hartford, Connecticut
  Malaria (*Plasmodium*);
  Babesiosis (*Babesia*)

Marzena Krawiec MD

Assistant Professor of Pediatrics,
University of Wisconsin Medical School,
Madison, Wisconsin
  Wheezing in Infants

John F. Kuttesch Jr. MD, PhD

Associate Professor of Pediatric Hematology/Oncology,
Vanderbilt University Medical Center,
Nashville, Tennessee
  Brain Tumors in Childhood

Catherine S. Lachenauer MD

Assistant Professor of Pediatrics,
Harvard Medical School;
Assistant in Medicine,
Children's Hospital,
Boston, Massachusetts
  Group B Streptococcus

Stephan Ladisch MD

Professor of Pediatrics and Biochemistry/Molecular Biology,
The George Washington University School of Medicine;
Scientific Director,
Children's Research Institute,
Children's National Medical Center,
Washington, DC
  Histiocytosis Syndromes of Childhood

Stephen LaFranchi MD

Professor of Pediatrics,

Oregon Health and Sciences University;
Staff Physician,
Doernbecher Children's Hospital,
Portland, Oregon
Disorders of the Thyroid Gland

Oren Lakser MD

Assistant Professor of Pediatrics,
Northwestern University;
Attending Physician,
Division of Pulmonary Medicine,
Children's Memorial Hospital,
Chicago, Illinois
Parenchymal Disease with Prominent Hypersensitivity, Eosinophilic Infiltration, or Toxin-Mediated Injury;
Slowly Resolving Pneumonia;
Bronchiectasis;
Pulmonary Abscess

Richard M. Lampe MD

Professor and Chair,
Department of Pediatrics,
Texas Tech University School of Medicine,
Lubbock, Texas
Osteomyelitis and Suppurative Arthritis

Philip J. Landrigan MD

Ethel H. Wise Professor and Chair,
Department of Community and Preventive Medicine,
Mount Sinai School of Medicine,
New York, New York
Chemical Pollutants

Charles T. Leach MD

Professor of Pediatrics,
Chief,
Division of Infectious Diseases,
University of Texas Health Science Center at San Antonio;
Attending Physician,
Christus Santa Rosa Children's Hospital and University Hospital,
San Antonio, Texas
Roseola (Human Herpesviruses 6 and 7);
Human Herpesvirus 8

Margaret W. Leigh MD

Professor of Pediatrics,
University of North Carolina;
Attending Physician,
University of North Carolina Hospitals,
Chapel Hill, North Carolina
Sarcoidosis

Robert F. Lemanske Jr. MD

Professor of Pediatrics and Medicine,
University of Wisconsin School of Medicine,
Madison, Wisconsin
Wheezing in Infants

Steven Lestrud MD

Professor of Pediatrics,
Feinberg School of Medicine,
Northwestern University;
Attending Physician,
Pediatric Pulmonary and Critical Care,
Chicago, Illinois
Bronchopulmonary Dysplasia

Donald Y. M. Leung MD, PhD

Professor of Pediatrics,
University of Colorado Health Sciences Center;
Head,
Division of Pediatric Allergy-Immunology,
National Jewish Medical and Research Center,
Denver, Colorado
Allergy and the Immunologic Basis of Atopic Disease;
Diagnosis of Allergic Disease;
Principles of Treatment of Allergic Disease; Allergic Rhinitis;
Childhood Asthma;
Atopic Dermatitis (Atopic Eczema);
Urticaria and Angioedema (Hives);
Anaphylaxis;
Serum Sickness;
Insect Allergy;
Adverse Reactions to Foods

Lenore S. Levine MD

Professor of Pediatrics,

College of Physicians and Surgeons,
Columbia University;
Attending Pediatrician,
New York Presbyterian Hospital,
New York, New York
Disorders of the Adrenal Glands

Stephen Liben MD

Associate Professor of Pediatrics,
McGill University;
Director,
Palliative Care Program,
The Montreal Children's Hospital of the McGill University Health Center,
Montreal, Quebec, Canada
Pediatric Palliative Care: The Care of Children with Life-Limiting Illness

Iris F. Litt MD

Marron and Mary Elisabeth Kendrick Professor of Pediatrics,
Stanford University School of Medicine;
Director,
Division of Adolescent Medicine,
Lucile Salter Packard Children's Hospital,
Palo Alto, California
Anorexia Nervosa and Bulimia

Andrew H. Liu MD

Associate Professor of Pediatric Allergy and Immunology,
Training Program Director,
National Jewish Medical and Research Center,
University of Colorado Health Sciences Center,
Denver, Colorado
Childhood Asthma

Sarah S. Long MD

Professor of Pediatrics,
Drexel University College of Medicine;
Chief,
Section of Infectious Diseases,
St. Christopher's Hospital for Children,
Philadelphia, Pennsylvania
Diphtheria (*Corynebacterium diphtheriae*);
Pertussis *(Bordetella pertussis* and *B. parapertussis)*

Daniel J. Lovell MD, MPH

Professor of Pediatrics,
University of Cincinnati Medical Center;
Associate Director,
Division of Pediatric Rheumatology,
Cincinnati Children's Hospital,
Cincinnati, Ohio
Treatment of Rheumatic Diseases

G. Reid Lyon PhD

Branch Chief,
Child Development and Behavior,
National Institute of Child Health and Human Development,
National Institutes of Health,
Rockville, Maryland
Specific Reading Disability (Dyslexia)

Joseph A. Majzoub MD

Professor of Pediatrics,
Harvard Medical School;
Chief,
Division of Endocrinology,
Children's Hospital Boston,
Boston, Massachusetts
Diabetes Insipidus;
Other Abnormalities of Arginine Vasopressin Metabolism and Action

Yvonne Maldonado MD

Associate Professor of Pediatrics,
Stanford University School of Medicine;
Attending Physician,
Lucile Salter Packard Children's Hospital,
Stanford, California
Measles;
Rubella;
Mumps

John C. Marini MD, PhD

Chief,
Heritable Disorders Branch,
National Institute of Child Health and Human Development,
National Institutes of Health,
Bethesda, Maryland
Osteogenesis Imperfecta

Morri Markowitz MD

Professor of Pediatrics,

Albert Einstein College of Medicine;
Attending Physician,
Pediatrics,
Division of Environmental Sciences,
Children's Hospital at Montefiore,
Montefiore Medical Center,
Bronx, New York
Lead Poisoning

Reuben K. Matalon MD

Professor of Pediatrics and Genetics,
University of Texas Medical Branch,
Galveston, Texas
Aspartic Acid (Canavan Disease)

Lawrence H. Mathers MD, PhD

Assistant Professor of Pediatrics and Anatomy,
Stanford University School of Medicine;
Attending Physician,
Lucile Salter Packard Children's Hospital,
Stanford, California
Effective Communication with Families in the PICU;
Pediatric Emergencies and Resuscitation;
Shock;
Transplantation Issues in the PICU;
Withdrawal or Withholding of Life Support, Brain Death, and Organ Procurement

Nancy J. Matyunas PharmD

Assistant Clinical Professor of Pediatrics,
Adjunct Instructor in Pharmacology and Toxicology,
University of Louisville,
Louisville, Kentucky
Poisonings:
Drugs, Chemicals, and Plants

Robert Mazor MD

Fellow,
Department of Pediatrics,
Division of Cardiology,
Feinberg School of Medicine,
Northwestern University;
Children's Memorial Hospital,
Chicago, Illinois
Pulmonary Edema

Paul L. McCarthy MD

Professor of Pediatrics,
Yale University School of Medicine;
Director,
Division of General Pediatrics,
Children's Hospital at Yale-New Haven,
New Haven, Connecticut
The Well Child;
Evaluation of the Sick Child in the Office and Clinic

Susanna A. McColley MD

Associate Professor of Pediatrics,
Feinberg School of Medicine,
Northwestern University;
Director,
Cystic Fibrosis Center,
Children's Memorial Hospital,
Chicago, Illinois
Disorders of the Lungs and Lower Airways;
Pulmonary Tumors;
Extrapulmonary Diseases with Pulmonary Manifestations

Margaret M. McGovern MD, PhD

Associate Professor of Human Genetics and Pediatrics,
Mount Sinai School of Medicine;
Attending Physician,
Pediatrics,
Mount Sinai Hospital,
New York, New York
Lipidoses;
Mucolipidoses;
Disorders of Glycoprotein Degradation and Structure

Kenneth McIntosh MD

Professor of Pediatrics,
Harvard Medical School;
Senior Associate in Medicine,
Children's Hospital Boston,
Boston, Massachusetts
Respiratory Syncytial Virus;
Adenoviruses;
Rhinoviruses

Rima McLeod MD

Jules and Doris Stein Research to Prevent Blindness Professor,
University of Chicago,
Visual Sciences and Ophthalmology Department,
Chicago, Illinois
Toxoplasmosis (*Toxoplasma gondii*)

Peter C. Melby MD

Associate Professor of Medicine,
Division of Infectious Diseases,
The University of Texas Health Science Center;
Staff Physician,
Department of Veterans Affairs Medical Center,
South Texas Veterans Health Care System,
San Antonio, Texas
Leishmaniasis (*Leishmania*)

Fred A. Mettler Jr. MD, MPH

Professor and Chair,
Department of Radiology,
University of New Mexico,
Albuquerque, New Mexico
Pediatric Radiation Injuries

Marian G. Michaels MD, MPH

Associate Professor of Pediatrics and Surgery,
University of Pittsburgh School of Medicine;
Children's Hospital of Pittsburgh,
Pittsburgh, Pennsylvania
Infections in Immunocompromised Persons

Henry Milgrom MD

Professor of Pediatrics,
University of Colorado Health Sciences Center;
Senior Faculty Member,
National Jewish Medical and Research Center,
Denver, Colorado
Allergic Rhinitis

Michael L. Miller MD

Associate Professor of Pediatrics,
Northwestern University Medical School;
Children's Memorial Medical Center,
Chicago, Illinois
Evaluation of Suspected Rheumatic Disease;
Treatment of Rheumatic Diseases;
Juvenile Rheumatoid Arthritis;
Ankylosing Spondylitis and Other Spondyloarthropathies;
Postinfectious Arthritis and Related Conditions;
Systemic Lupus Erythematosus;
Scleroderma;
Vasculitis Syndromes;
Musculoskeletal Pain Syndromes;
Miscellaneous Conditions Associated with Arthritis

Robert R. Montgomery MD

Professor of Pediatrics and Vice Chair of Research,
Medical College of Wisconsin;
Senior Investigator,
Blood Center of Southeastern Wisconsin,
Milwaukee, Wisconsin
Hemorrhagic and Thrombotic Diseases

Anna-Barbara Moscicki MD

Professor of Pediatrics,
University of California, San Francisco,
School of Medicine,
San Francisco, California
Human Papillomaviruses

Hugo W. Moser MD

Professor of Neurology and Pediatrics,
Kennedy Krieger Institute,
The Johns Hopkins University School of Medicine,
Baltimore, Maryland
Disorders of Very Long Chain Fatty Acids

Joseph L. Muenzer MD

Associate Professor of Pediatrics,
University of North Carolina School of Medicine,
Chapel Hill, North Carolina
Mucopolysaccharidoses

Flor M. Munoz MD

Assistant Professor of Pediatrics,
Baylor College of Medicine;
Texas Children's Hospital,
Houston, Texas
Tuberculosis (*Mycobacterium tuberculosis*)

James R. Murphy PhD

Pediatric Infectious Diseases,
University of Texas Health Science Center,
Houston, Texas
Cholera (*Vibrio cholerae*);
Campylobacter;
Yersinia;
Aeromonas and *Plesiomonas*

Martin G. Myers MD

Professor of Pediatrics,
University of Texas Medical Branch;
Children's Hospital,
Galveston, Texas
Varicella-Zoster Virus

Robert D. Needlman MD

Adjunct Associate Professor of Pediatrics,
Case Western Reserve University School of Medicine;
Attending Physician,
MetroHealth Medical Center,
Cleveland, Ohio
Growth and Development

Leonard B. Nelson MD

Associate Professor of Ophthalmology and Pediatrics,
Jefferson Medical College;
Co-Director,
Department of Pediatric Ophthalmology,
Wills Eye Hospital,
Philadelphia, Pennsylvania
Disorders of the Eye

Robert M. Nelson MD, PhD

Associate Professor of Anesthesia and Pediatrics,
University of Pennsylvania School of Medicine;
Chair,
Committees for the Protection of Human Subjects,
Children's Hospital of Philadelphia,
Philadelphia, Pennsylvania
Ethics in Pediatric Care

Vicky Lee Ng MD

Assistant Professor of Pediatrics,
University of Toronto;
Staff Physician,
Division of Gastroenterology and Nutrition,
Pediatric Academic Multi-Organ Transplant (PAMOT) Program,
Hospital for Sick Children,
Toronto, Ontario, Canada
Manifestations of Liver Disease

John F. Nicholson MD

Associate Professor of Pediatrics and Pathology,
Columbia University;
Associate Attending Pediatrician,
Children's Hospital of New York-Presbyterian Hospital,
New York, New York
Laboratory Testing in Infants and Children;
Reference Ranges for Laboratory Tests and Procedures

Zehava Noah MD

Associate Professor in Pediatrics,
Feinberg School of Medicine,
Northwestern University;
Attending Physician,
Children's Memorial Hospital,
Chicago, Illinois
Chronic Severe Respiratory Insufficiency

Lawrence M. Nogee MD

Associate Professor of Pediatrics,
The Johns Hopkins,
University School of Medicine;
Attending Neonatologist,
Johns Hopkins Children's Center,
Baltimore, Maryland
Pulmonary Alveolar Proteinosis;
Inherited Disorders of Surfactant Protein Metabolism

Theresa J. Ochoa MD

University of Texas-Houston Health Science Center;
Pediatric Disease Fellow,
Memorial Hermann Children's Hospital,
Houston, Texas
Escherichia coli

Robin K. Ohls MD

Associate Professor of Pediatrics,
Division of Neonatology,
University of New Mexico School of Medicine;
Department of Pediatrics/Neonatology,
Children's Hospital of New Mexico,
Albuquerque, New Mexico
Development of the Hematopoietic System

Scott E. Olitsky MD

Associate Professor of Ophthalmology,
University of Missouri at Kansas City;
Chief of Ophthalmology,
The Children's Mercy Hospital,
Kansas City, Missouri
Disorders of the Eye

Karen Olness MD

Professor of Pediatrics, Family Medicine, and International Health,
Case Western Reserve University School of Medicine;
Director,
Rainbow Center for International Child Health,
Rainbow Babies and Children's Hospital,
Cleveland, Ohio
Child Health in the Developing World

Susan Orenstein MD

Professor and Chief,
Pediatric Gastroenterology,
University of Pittsburgh School of Medicine;
Children's Hospital of Pittsburgh,
Pittsburgh, Pennsylvania
The Esophagus

Gary D. Overturf MD

Department of Pediatrics,
University of New Mexico Medical Center,
Albuquerque, New Mexico
Streptococcus pneumoniae (Pneumococcus)

Judith A. Owens MD, MPH

Associate Professor of Pediatrics,
Brown Medical School;
Director,
Pediatrics Sleep Disorders Clinic,
Hasbro Children's Hospital,
Providence, Rhode Island
Sleep Disorders

Lauren M. Pachman MD

Professor of Pediatrics,
Division of Immunology/Rheumatology,
Feinberg School of Medicine,
Northwestern University;
Interim Division Head,
Disease Pathogenesis Program,
Children's Memorial Institute of Education and Research (CMIER),
Children's Memorial Hospital,
Chicago, Illinois
Juvenile Dermatomyositis;
Vasculitis Syndromes

Regina M. Palazzo MD

Assistant Professor of Pediatrics,
Yale University School of Medicine;
Director,
Cystic Fibrosis Center,
Attending Physician,
Yale-New Haven Children's Hospital,
New Haven, Connecticut
Diagnostic Approach to Respiratory Disease

Demosthenes Pappagianis MD, PhD

Professor,
Department of Medical Microbiology and Immunology,
University of California, Davis,
School of Medicine,
Davis, California
Coccidioidomycosis (*Coccidioides immitis*)

Diane E. Pappas MD

Associate Professor of Pediatrics,
University of Virginia School of Medicine,
Charlottesville, Virginia
Sinusitis;
Retropharyngeal Abscess,
Lateral Pharyngeal (Parapharyngeal) Abscess, and Peritonsillar Cellulitis/Abscess

Jack L. Paradise MD

Professor of Pediatrics, Family Medicine, and Clinical Epidemiology,
Professor of Otolaryngology,
University of Pittsburgh School of Medicine;
Attending Staff,
Children's Hospital of Pittsburgh,
Pittsburgh, Pennsylvania
Otitis Media

John S. Parks MD, PhD

Professor of Pediatrics,
Emory University School of Medicine;
Director,
Pediatric Endocrinology,
Egleston Children's Hospital,
Atlanta, Georgia
Hormones of the Hypothalamus and Pituitary;
Hypopituitarism

Sheral S. Patel MD

Assistant Professor of Pediatric Infectious Diseases,
Case Western Reserve University School of Medicine;
Attending Physician,
Rainbow Babies and Children's Hospital,
University Hospitals of Cleveland,
Cleveland, Ohio
Ascariasis (*Ascaris lumbricoides*);
Trichuriasis (*Trichuris trichiura*);
Enterobiasis (*Enterobius vermicularis*);
Strongyloidiasis (*Strongyloides stercoralis*);
Lymphatic Filariasis (*Brugia malayi, Brugia timori,* and *Wuchereria bancrofti*);
Other Tissue Nematodes;
Toxocariasis (Visceral and Ocular Larva Migrans);
Trichinosis (*Trichinella spiralis*)

Alberto Peña MD

Professor of Surgery,
Albert Einstein College of Medicine,
Bronx, New York;
Chief,
Pediatric Surgery,
Schneider Children's Hospital,
North Shore Long Island Jewish Health System,
New Hyde Park, New York
Surgical Conditions of the Anus, Rectum, and Colon

James M. Perrin MD

Professor of Pediatrics,
Harvard Medical School;
Director,
Division of General Pediatrics,
Director,
Center for Child and Adolescent Health Policy,
Massachusetts General Hospital for Children,
Boston, Massachusetts
Developmental Disabilities and Chronic Illness;
Chronic Illness in Childhood

Michael A. Pesce PhD

Columbia University College of Physicians and Surgeons;
Director,
Specialty Laboratory,
New York-Presbyterian Hospital at Columbia Medical Center,
New York, New York
Laboratory Testing in Infants and Children;
Reference Ranges for Laboratory Tests and Procedures

Georges Peter MD

Professor of Pediatrics,
Vice Chair for Faculty Affairs,
Brown Medical School;
Director,
Division of Pediatric Infectious Diseases,
Rhode Island Hospital,
Providence, Rhode Island
Immunization Practices

John Peters DO

Assistant Professor of Pediatric Gastroenterology,
University of Pittsburgh School of Medicine;
Children's Hospital of Pittsburgh,
Pittsburgh, Pennsylvania
The Esophagus

Ross E. Petty MD, PhD

Professor and Head of Pediatrics,
University of British Columbia;
British Columbia Children's Hospital,
Vancouver, Canada
Ankylosing Spondylitis and Other Spondyloarthropathies

Larry K. Pickering MD

Professor of Pediatrics,
Emory University School of Medicine;
Senior Advisor to the Director,
National Immunization Program,
Centers for Disease Control and Prevention,
Atlanta, Georgia
Giardiasis and Balantidiasis;
Child Care and Communicable Diseases;
Gastroenteritis;
Viral Hepatitis

Dwight A. Powell MD

Professor of Pediatrics,
The Ohio State University,
College of Medicine and Public Health;
Chief,
Section of Pediatric Infectious Diseases,
Children's Hospital,
Columbus, Ohio
Hansen Disease (*Mycobacterium leprae*);
Nontuberculous Mycobacteria;
Mycoplasmal Infections

Part 1 - The Field of Pediatrics

1

Chapter 1 - Overview of Pediatrics

Richard E. Behrman

Pediatrics is concerned with the health of infants, children, and adolescents; their growth and development; and their opportunity to achieve full potential as adults. As physicians who assume a responsibility for children's physical, mental, and emotional progress from conception to maturity, pediatricians must be concerned with social and environmental influences, which have a major impact on the health and well-being of children and their families, as well as with particular organ systems and biologic processes. The young are often among the most vulnerable or disadvantaged in society, and thus their needs require special attention.

SCOPE AND HISTORY OF PEDIATRICS AND VITAL STATISTICS

More than a century ago, pediatrics emerged as a medical specialty in response to increasing awareness that the health problems of children differ from those of adults and that a child's response to illness and stress varies with age. The emphasis and scope of pediatrics continue to change, but these basic observations remain valid.

The health problems of children and youth vary widely among the nations of the world depending on a number of factors, which are often interrelated. These factors include (1) the prevalence and ecology of infectious agents and their hosts; (2) climate and geography; (3) agricultural resources and practices; (4) educational, economic, social, and cultural considerations; (5) stage of industrialization and urbanization; and (6) in many instances, the gene frequencies for some disorders.

Not only do problems differ in various parts of the world, but priorities do also, because they must reflect local concerns, resources, and needs. Assessment of the state of health of any community must begin with a description of the incidence of illness and must continue with studies that show the changes that occur with time and in response to programs of prevention, case finding, therapy, and adequate surveillance. As contemporary problems in any community yield to study and to improved management, new problems become the foci of the attention and efforts of pediatric clinicians and research workers. Accordingly, with time, the relative importance of the various causes of childhood morbidity and mortality may undergo major changes.

In the late 19th century in the United States, of every 1,000 children born alive, 200 might be expected to die before the age of 1 yr of conditions such as dysentery, pneumonia, measles, diphtheria, and whooping cough. The efforts of pediatricians, combined with those of scientists and pioneers in public health, have led to such better understanding of the origin and management of many problems of infants that in the past half century the infant mortality rate in the United States has decreased from around 75/1,000 live births in 1925 to approximately 6.9/1,000 in 2000. Both neonatal (<1 mo) and postneonatal (1–11 mo) mortality have had major reductions. However, most of the decline in infant mortality since 1970 is attributable to a decrease in the birthweight-specific infant mortality rate related to pediatric care, not to the prevention of low-birthweight births. The majority of deaths of infants younger than 1 yr of age occur within the first 28 days of life, most of these within the first 7 days; moreover, a large proportion of those within the first 7 days occur within the 1st day. However, an increasing number of severely ill infants born at very low birthweight survive the neonatal period and die later in infancy of neonatal disease, its sequelae, or its complications. Tables 1–1 and 1–2 show the persistent disproportionately high death rate within the 1st yr, compared with the remainder of childhood.

Postneonatal infant mortality for the United States in 2000 was 2.3/1,000 live births (4.7/1,000 for black infants and 1.9/1,000 for white infants). The leading cause of death in this age group was sudden infant death syndrome, followed in order by congenital anomalies, perinatal conditions, respiratory system diseases, accidents, and infectious diseases. Maternal risk characteristics, such as unmarried status, adolescence, high parity, and less than 12 yr of education, are correlated significantly with increased risk of postneonatal mortality and morbidity and low birthweight.

In developed countries early in the 20th century, efforts at control of infectious disease began to be complemented by better understanding of nutrition. New and continuing discoveries in these areas led to establishment of public well child clinics for low-income families. Along with acute infections and the chronic disturbances associated with deficits of calories, vitamins, minerals, or proteins, the acute nutritional and metabolic disturbances that accompany acute diarrhea received attention.

In the middle years of the 20th century, a profound revolution in child health was brought about by the introduction of antibacterial chemicals and antibiotic agents. With improved control of infectious disease through both prevention and treatment and with other scientific and technical advances, pediatric medicine increasingly turned its attention to a broad spectrum of conditions, each affecting relatively small numbers of children. These included both potentially lethal conditions and temporarily or permanently handicapping conditions; among these disorders were

leukemia, cystic fibrosis, diseases of the newborn infant, congenital heart disease, mental retardation, genetic defects, rheumatic diseases, renal diseases, and metabolic and endocrine disorders.

The last two decades of the 20th century were marked by accelerated understanding of and new approaches to the management of many disorders as a consequence of advances in molecular biology, genetics, and immunology. Increasing attention also has been given to behavioral and social aspects of child health, ranging from re-examination of child-rearing practices to creation of major programs aimed at prevention and management of abuse and neglect of infants and children. Developmental psychologists, child psychiatrists, neuroscientists, sociologists, anthropologists, ethnologists, and others have brought us new insights into human potential, including new views of the importance of the environmental circumstances during pregnancy, surrounding

birth, and in the early years of child rearing. However, during the latter years of the 20th century there was also a resurgence of some of the infectious diseases previously controlled in developed countries, such as tuberculosis and syphilis; the emergence of new infectious pathogens, such as the human immunodeficiency virus; and the recognition of new disorders related to innovative therapies. In addition, in developing countries, many of the disorders facing children earlier in this century persist, sometimes aggravated by war and famine.

Table 1–3 shows the leading causes of death in various age groups in 1999. The problems of these children have changed significantly in the United States over a generation. Table 1–3 highlights the impact of violent deaths on mortality in older children, adolescents, and young adults.

Tables 1–1 , 1–2 , and 1–4 show that the nonwhite children and other racial and ethnic groups of children in the United States have not fully benefited from the changes in infant mortality in this century owing to various socioeconomic and other disadvantages that have resisted the efforts of many who have struggled to reduce this disparity, including many pediatricians. Similar disparities between races and ethnic groups occur in several indices of health, such as rates of diseases of the heart and homicides.

In the United States, existing programs for meeting child health problems are not available to all families in need, with gaps between eligibility for public support and parents' ability to pay for services. Needed services are often either nonexistent or fragmented among programs, agencies, or policies. Programs are often poorly coordinated, and the data collection is inadequate. The resources available for maternal and child health care services are also generally inadequate. These findings reflect a need, not just in the United States but in many other parts of the world as well, for continuing re-examination and revision of the system of health care, especially with regard to its impact on the health status of children.

These problems are exacerbated by social and demographic changes in the United States. By 1999, 27% of all children younger than 18 yr of age were living with one parent, more than twice the number of such children in 1970. Of these one-parent families, 85% consisted of children living with their mother. There are substantial differences among children: 56% of black, 32% of Hispanic, 22% of white, and 36% of Native American children live with one parent. Furthermore, in 1997, 57% of women with children younger than 3 yr of age, 64% with children younger than 6 yr, and 74% with children ages 6–17 yr worked full time or part time outside the home. In 1994, children younger than 5 yr with employed mothers were being cared for in a variety of settings: day care center or preschool (29%), non-relative in a home (20%), and relative in a home (43%). In 1996, welfare reform increased incentives for women with low incomes to enter the workforce and provided more support for child care.

Family income is central to the health and well-being of children. Children living in poor families are much more likely than children living in rich or middle-class families to experience material deprivation and poor health, die during childhood, score lower on standardized tests, be retained in grade, drop out of school, have out-of-wedlock births, experience violent crime, end up as poor adults, and suffer other undesirable outcomes. In 1998, 18% of all children in the United States lived in poverty[*]: white, 14%; black, 36%, Hispanic, 34%. Eight percent of children in the United States live in extreme poverty (in families with incomes less than 50% of the poverty line[*]). Many of these children live their entire childhood in poverty. Children who live in single-parent families with poorly educated, young, minority (particularly black), or disabled adults are more likely to be poor and live in poverty longer than those who do not live in such families.

The aforementioned findings have generated three sets of goals. The first set includes that all families have access to

* Weighted average poverty threshold in 1998 in the United States was $16,530 for four-person families.

adequate perinatal, preschool, and family-planning services; that governmental activities be effectively coordinated at national and local levels; that services be so organized that they reach populations at special risk; that there be no insurmountable or inequitable financial barriers to adequate care; that the health care of children have continuity from prenatal through adolescent age periods; and that every family ultimately have access to *all* necessary services, including developmental, dental, genetic, and mental health services. A second set of goals addresses the needs for reducing accidents and environmental risks, for meeting nutritional needs, and for health education aimed at fostering health-promoting lifestyles. A third set of goals covers needs for research in biomedical and behavioral science, in fundamentals of bioscience and human biology, and in the particular problems of mothers and children.

The unfinished business in the quest for physical, mental, and social health in the community is illustrated by the disparities with which deaths due to disease, injuries, and violence

are distributed among white, black, and Hispanic children. Homicide has become a major cause of adolescent deaths and has increased in rate also among the very young, in whom the increase may in part represent the more accurate identification of child abuse (Chapter 35); among adolescents it may reflect unresolved social tensions, the epidemic of substance abuse (especially cocaine and crack), and an unhealthy preoccupation with violence in our society. Some of the issues underlying these problems are discussed in Chapters 24 , 34 , 39 , and Part XII .

PATTERNS OF HEALTH CARE

Children (0–21 yr) make up slightly less than one third of the population of the United States. The number of births has been increasing since 1976 and is expected to continue to increase at 1–2% annually. There were 3,959,417 live births in 1999. Table 1–5 indicates the distribution of children in the population by age. The population of children has been increasing since 1950. However, the proportion of children is decreasing relative to the adult population. The racial, ethnic, and cultural diversity among children is increasing significantly.

In 1999, about 117 million visits were made to physicians' offices and 15 million visits were made to hospital outpatient departments by children younger than 15 yr; an additional 60 million and 8 million visits were made by children and young adults (15–24 yr), respectively. The principal diagnoses accounting for almost 40% of these visits were well child visit (15%), middle-ear infection (12%), and injury (10%). The rate of ambulatory visits by children and youth decreases with increasing age. The opposite occurs with adults. In contrast to the large number of children seen in ambulatory settings, 2,258,000 children younger than 15 yr (excluding newborns) were admitted to acute care hospitals in the United States in 1999. Nonwhite children are more likely than white children to use hospital

U.S. Bureau of Census.

facilities for their ambulatory care, and well child visits are almost 80% higher among white infants than black infants.

Hospitals, particularly in urban areas, are sources of both routine and intensive child care, with medical and surgical services that may range from immunization and developmental counseling to open heart surgery and renal transplantation. Clinical conditions and procedures requiring intensive care are likely to be clustered in university-affiliated centers serving as regional resources. The hospitalization rates for children (excluding newborn infants) are less than those of adults younger than 65 yr of age, except during the first year of life. In 1999, the rates per 1,000 population were as follows: younger than 1 yr, 208.5; 1–4 yr, 46.6; 5–14 yr, 22.2; 15–19 yr, 60.0 (excluding obstetrics). The rate of hospitalization and lengths of hospital stay have declined significantly for children and adults during the past decade. Children represent less than 8% of the total acute hospital discharges, and in children's hospitals about 70% of admissions are for chronic conditions. Ten to 12% of pediatric hospitalizations are related to birth defects and genetic diseases.

PLANNING AND IMPLEMENTING A SYSTEM OF CARE

Physicians caring for children have been increasingly called on to advise in the management of disturbed behavior of children and youth or problematic relationships between child and parent, child and school, or child and community. They are increasingly concerned with problems of mental, social, and societal health. There is also an increasing concern about disparities in how the benefits of what we know about child health reach various groups of children. Just as in many developing countries, so in the United States does the health of children lag far behind what it could be if the means and will to apply current knowledge were focused on the health of children. The medical problems of children are often intimately related to problems of mental and social health. The children most at risk are disproportionately represented among ethnic minority groups. Pediatricians have a responsibility to aggressively address problems such as these.

Linked with these views of the broad scope of pediatric concern is the concept that access to at least a basic level of quality services to promote health and treat illness is a right of every person. Among children in the United States, having health insurance is strongly associated with access to primary care. The failure of health services and health benefits to reach all who need them has led to re-examination of the design of health care systems in many countries, but unresolved problems remain in most health care systems, such as the maldistribution of physicians, institutional unresponsiveness to the perceived needs of the individual, failure of medical services to adjust to the need and convenience of patients, and deficiencies in health education. Efforts to make the delivery of health care more efficient and effective have led imaginative pediatricians to create new categories of health care providers, such as pediatric nurse practitioners, and to participate in new organizations for providing care to children, such as various managed care arrangements.

New insights into the needs of children have reshaped the child health care system in other ways. Growing understanding of the need of infants for certain qualities of stimulation and care has led to restudy and revision of the care of newborn infants (Chapters 9 and 83) and of procedures leading to an adoption or to placement with foster families (Chapters 30 and 31). For handicapped children, the massive

centralized institutions of past years are being replaced by community-centered arrangements offering a better opportunity for these children to achieve their maximum potential. Pediatricians have been involved in shaping these and other institutions that provide services to children, and their insights and active contributions will continue to be needed.

COSTS OF HEALTH CARE

The growth of high technology, the increasing number of people older than 65 yr, the redesign of health institutions (particularly with respect to the needs for and the uses of personnel), the public's demand for medical services, and the manner in which the costs of health care are paid have driven the costs of health care in the United States up to a point at which they represent a significant proportion of the gross national product. Although children (0–18 yr) represent about 30% of the population, they account for only about 14% of the personal health care expenditures, or about 60% of adult per capita expenditures. Efforts to contain costs have led to revisions of the way in which physicians and hospitals are paid for services. Limits have been set on the fees for some services, capitated prepayment and various managed care systems flourish, a program of reimbursement (diagnosis-related groups [DRGs]) based on the diagnosis rather than on the particular services rendered to an individual patient has been implemented, and a relative value scale for varying rates of payment among different physician services has been instituted. These and other changes in the system of financing health services raise important ethical and professional issues for pediatricians to address (Chapter 2).

EVALUATION OF HEALTH CARE

The shaping of health care systems to meet the needs of children and their families requires accurate statistical data and difficult decisions in setting priorities. Along with growing concerns about the design and cost of health care systems and the ability to distribute health services equitably has come increasing concern about the quality of health care and about its efficiency and effectiveness. There are large local and regional variations among similar populations of children in the rates of use of procedures and technology and of hospital admissions. These variations require continuing evaluation and explanation in terms of the actual impact of medical and surgical services on health status and the outcome of illness.

GROWTH OF SPECIALIZATION

The amount of information relevant to child health care is rapidly expanding, and no person can become master of it all. Physicians are increasingly dependent on one another for the highest quality of care for their patients; group practices in pediatrics are common in the United States, and although the vast majority of pediatricians are primary care generalists, as many as 25% claim an area of special knowledge and skill.

The growth of specialization within pediatrics has taken a number of different forms: Interests in problems of *age groups* of children have created neonatology and adolescent medicine; interests in *organ systems* have created pediatric cardiology, neurology, child development, allergy, hematology, nephrology, gastroenterology, child psychiatry, pulmonology, endocrinology, and specialization in metabolism and genetics; interests in the *health care system* have created pediatricians devoted to ambulatory care, emergency care, and intensive care; and finally, multidisciplinary subspecialties have grown up around the problems of *handicapped children*, to which pediatrics, neurology, psychiatry, psychology, nursing, physical and occupational therapy, special education, speech therapy, audiology, and nutrition all make essential contributions. This growth of specialization has been most conspicuous in university-affiliated departments of pediatrics and medical centers for children.

NEED FOR CONTINUING SELF-EDUCATION

The explosion of information has also created a need for continuing education, which was felt much less keenly in earlier years, when the new information in any field of medicine was easily accessible through a relatively small number of journals, texts, or monographs. Now, relevant information is so widely scattered among the many published journals that elaborate electronic data systems are necessary to make it accessible. The Internet has dramatically improved access to information by physicians and patients, but judgment about the quality, clinical significance, and appropriate use of such information is a continuing challenge. New auditory and visual aids to learning abound, as do postgraduate courses through which participating physicians can be brought up to date on various aspects of child health care. The American Board of Pediatrics and the American Academy of Pediatrics have arranged for close linkage of continuing education of pediatricians to recertification in pediatrics.

There is no touchstone through which physicians can ensure that the process of their own continuing education will keep them abreast of advancing knowledge in the field, but they must find a way to base their decisions on the best available scientific evidence if they are to discharge their responsibility to their patients. An essential element of this process may be for physicians to take an *active* role, such as participating in medical student and resident education. Efforts in continuing self-education will also be fostered, for example, if clinical problems can be made a stimulus for a review of standard literature, alone or in consultation with an appropriate colleague or consultant. This continuing review will do much to identify those inconsistencies or contradictions that will indicate, in the ultimate best interest of patients, that things are not what they seem or have been said to be. Physicians still learn most from their patients, but this will not be the case if they fall into the easy habit of accepting their patients' problems casually or at face value because the problems appear to be simple.

The tools that physicians must use in dealing with the problems of children and their families fall into three main categories: *cognitive* (up-to-date factual information about diagnostic and therapeutic issues, available on recall or easily found in readily accessible sources, and the ability to relate this information to the pathophysiology of their patients in the context of individual biologic variability); *interpersonal or manual* (e.g., the ability to carry out a productive interview, execute a reliable physical examination, perform a deft venipuncture, or manage cardiac arrest or resuscitation of a depressed newborn infant); and *attitudinal* (the physician's unselfish commitment to the fullest possible implementation of knowledge and skills on behalf of children

and their families in an atmosphere of empathic sensitivity and concern). With regard to this last category, it is important that children participate with their families in informed decision-making about their own health care in a manner appropriate to their stage of development and the nature of the particular health problem.

The workaday needs of professional persons for knowledge and skills in care of children vary widely. Primary care physicians need depth in developmental concepts and in the ability to organize an effective system for achieving quality and continuity in assessing and planning for health care during the entire period of growth. They may often have little or no need for immediate recall of esoterica. On the other hand, consultants or subspecialists not only need a comfortable grasp of esoterica within their field and perhaps within related fields but also must be able to cope with controversial issues with flexibility that will permit adaptation of various points of view to the best interest of their unique patient.

At whatever level of care (primary, secondary, or tertiary) or in whatever position (student, pediatric nurse practitioner, resident pediatrician, practitioner of pediatrics or family medicine, or pediatric or other subspecialists), professional persons dealing with children must be able to identify their roles of the moment and their levels of engagement with a child's problem; each must determine whether his or her experience and other resources at hand are adequate to deal with this problem and must be ready to seek other help when they are not. Among the

necessary resources are general textbooks, more detailed monographs in subspecialty areas, selected journals, audiovisual and Internet materials, and, above all, colleagues with exceptional or complementary experience and expertise. The intercommunication of all these levels of engagement with medical and health problems of children offers the best hope of bringing us closer to the goal of providing the opportunity for all children to achieve their maximum potential.

Chapter 2 - Ethics in Pediatric Care

Robert M. Nelson
Norman Fost

The proper scope of parental decision-making is bounded by the concept of a child's best interest and by the emerging desire and capacity for autonomy or self-determination of an older child or adolescent. In addition, the pediatric clinician has an independent professional obligation to act in a child's “best interest,” thus creating the possibility of conflict among child, parent, and clinician. The approach to the ethical issues that arise in pediatric practice must include respect for both a parent's responsibility for the life and health of a child and a child's developing capacity and autonomy. Further complexity is added by the varying social, cultural, and religious views of the role of family, parental authority, appropriate methods for disciplining a child, the age of majority, and alternative approaches to health care.

INFORMED CONSENT, PARENTAL PERMISSION, AND CHILD ASSENT

A competent adult patient has the right to decide, after consultation with a physician, which medical interventions he or she will or will not accept. This right of self-determination (or autonomy) based on personal preferences and values is reflected in the doctrine of voluntary and informed consent. This doctrine, however, has limited direct application to children and adolescents who lack the decisional capacity or legal empowerment to give informed consent to medical care. The capacity for informed decision-making in health care is generally thought to involve the ability to understand and communicate, to reason and deliberate, and to analyze conflicting elements of a decision using a set of personal values. The age at which a competent patient may legally exercise voluntary and informed consent for medical care varies from state to state and may be limited to specific conditions, for example, sexually transmitted diseases, family planning, and drug or alcohol abuse.

In contrast to decisions about one's own care, a parent's right to direct a child's medical care is more limited. It is constrained both by the child's best interest and the independent obligation of clinicians to act in the child's best interest, even if this places them in conflict with a parent. The concept of parental permission (rather than consent) reflects this shared decision-making involved in pediatric health care. In any given instance, the decision of what is or is not in a child's best interest may be difficult, especially given the diverse views of acceptable child rearing and child welfare. Parents are (and should be) granted wide discretion in raising their children. Nevertheless, in cases involving a substantial risk of harm, the moral focus should be on what is best for the child, not on a parental right to decide.

Respect for children must account for both a child's vulnerability and developing capacity. Thus, this respect encompasses both the protective role of parental permission and the developmental role of child assent. At times, respect for a child requires overriding a child's dissent when a proposed intervention is essential to his or her welfare. Otherwise, assent (i.e., the child's affirmative agreement) should be obtained and dissent honored. In seeking a child's assent, a clinician should help a child understand his or her condition, tell a child what he or she can expect, assess a child's understanding and whether a child feels pressured to assent, and solicit a child's willingness to participate.

TREATMENT OF CRITICALLY ILL CHILDREN

Most children who are critically ill recover and are able to return to an acceptable quality of life. However, some children either respond partially or fail to respond to life-sustaining medical treatment (LSMT), progressing toward death over a time span ranging from minutes to years (see Chapter 38). Under these circumstances, a number of questions arise. Should one initiate or continue LSMT? How does one arrive at this decision? What treatments should be provided as part of palliative care? Is there any difference between starting and stopping a medical intervention? What about specific interventions such as cardiopulmonary resuscitation or artificially provided hydration and nutrition? Should newborn infants and older children be treated differently when considering LSMT?

Transitioning from “Cure” to “Care.”

The provision of LSMT assumes that the burden of treatment is justified by the anticipated benefit of returning to or sustaining an acceptable quality of life. As the anticipated quality of the outcome deteriorates or becomes increasingly unlikely, or as the burden of treatment becomes intolerable, we ask whether continued LSMT makes sense. Answering this question is difficult, involving a range of possible outcomes, complex estimates of probabilities, differing values of each outcome, and dealing with uncertainty and hope. Medical technology and other treatments should only be used when the benefits for the child outweigh the burdens, especially for children living with life-threatening or terminal conditions.

The concept of *futility* has been invoked in support of the unilateral forgoing of LSMT by health care professionals over the objections of patients and family. Although it seems self-evident that clinicians should not provide futile (or useless) interventions, the application of this principle is problematic if used to justify unilateral professional action based on values that are not shared by the affected patient or family. The concept of futility should be reserved for those interventions that will not in fact achieve a given physiologic outcome. The appeal to futility should not be used to short-circuit the collaborative process by which medical interventions are seen to be disproportionately burdensome.

Life-Sustaining Medical Treatment or Palliative Care?

A rigid distinction between LSMT and palliative care (Chapter 38) may be difficult to

draw in any given instance, and their integration is often desirable. LSMT can be broadly defined as any intervention that may prolong the life of a patient or alter substantially the expected progression toward death. Examples of LSMT include organ transplantation, ventilator therapy, dialysis, and

treatment with vasoactive medications, or more mundane interventions such as antibiotics, chemotherapy, and artificially provided nutrition and hydration. Palliative care interventions focus on the relief of symptoms and conditions that may detract from a child's (and family's) quality of life regardless of the impact on a child's underlying disease process. The control of pain and other symptoms, as well as concern for the psychological or spiritual problems associated with life-threatening or terminal disease, are usually considered palliative and are often appropriate during LSMT. Certain LSMT may also be appropriate in the palliative management of the dying child (see Chapter 38 for full discussion).

Withholding and Withdrawing Life-Sustaining Treatment.

(See Chapter 64 .) A palliative care plan involves the assessment of available diagnostic and therapeutic interventions based on the goal of improving a child's quality of life while living with a life-threatening or terminal disease. Some interventions that are currently being provided may be withdrawn. Other interventions that are not being provided may be withheld. Although the prevailing view is that there is no moral distinction between withholding or withdrawing interventions that are not medically indicated, the uncertainty inherent in predicting a child's response to treatment suggests that withdrawing treatment based on a child's failure to respond is morally preferable to withholding that same treatment. In addition, withholding treatment out of concern that the withdrawal of that same treatment in the future would be more difficult risks undertreating some children who would in fact respond favorably to that treatment. The withdrawal of LSMT may be psychologically more stressful than withholding LSMT, and may add complexity as the moral values associated with treatment of any given child may shift over time.

The decision to not attempt cardiopulmonary resuscitation is often the initial focus of discussion with parents of children living with life-threatening or terminal conditions. Obtaining a “do not attempt resuscitation” order (DNAR) may become a symbol of a clinician's success at negotiating limits to LSMT with a child's parents and eclipse other interventions that should be considered in providing for a child's comfort. The decision for a DNAR order should not imply a decision to withhold or withdraw other aspects of providing medical treatment, such as oxygen, suctioning, pain medications, and so forth. In addition, the decision is not irrevocable. The DNAR order should be part of a comprehensive plan of care that is periodically reviewed and that should be respected in all aspects of a child's care, including schooling. The extension of DNAR orders for children to the out-of-hospital setting can be an important component of providing comprehensive care. Mechanisms and laws should be in place for DNAR orders to be respected in schools and the prehospital emergency medical system.

One of the more difficult issues in withholding or withdrawing LSMT is the provision of artificial hydration and nutrition. Any person sufficiently dependent on the care of others will die as a result of not receiving hydration and nutrition. Some contend that the artificiality of some methods of providing hydration and nutrition (such as the use of a gastrostomy tube or intravenous hyperalimentation) indicates that they may be withheld or withdrawn as with any LSMT. A more compelling argument is that nutrition and hydration are not in a particular child's best interest regardless of the method of administration. Some states require “clear and convincing evidence” of a patient's prior wishes in order to withdraw such LSMT from patients who are either incompetent or in a permanent vegetative state. This “substituted judgment” is not possible in young children or in patients who became incompetent before expressing such wishes. Although there are legal cases that have allowed the removal of artificial nutrition and hydration based on a patient's “best interests,” the rulings are generally in regard to adult patients and are thus of uncertain pediatric applicability.

The decision to withhold or withdraw LSMT does not necessarily imply an intent or choice to hasten a child's death. One can choose how to live while dying without choosing death, even when death is the anticipated outcome of one's choice. The provision of adequate sedation and analgesia to relieve rapidly progressive symptoms such as pain and dyspnea need not be interpreted as causing a child's death.

If a decision has been made that continued survival is not in a patient's best interest, it would seem irrelevant whether he or she died by forgoing LSMT or the administration of a drug. Indeed, the administration of a lethal drug might be preferable because of the opportunity to minimize suffering. However, the reasons for opposition to such decisions are only partly related to concerns for the interests of patients. The objections are based, in part, on the swiftness and irreversibility of action, precluding the possibility of changing course if it is discovered that the decision was wrong. The greater concern, however, has been for “slippery slope” effects: the claim that lowering the barrier against killing will make it easier for physicians to kill others, that boundaries will become less distinct, and that patients without a clear interest in dying will be harmed. Some contend that the current experience in The Netherlands lends some support to this concern. In addition, the backlash against physician-assisted suicide may render the appropriate provision of palliative care more difficult through fear of legal prosecution based simply on the dose of sedatives or narcotics administered.

Disabled Newborns and LSMT.

In 1982, an infant with Down syndrome and esophageal atresia was allowed to die at 6 days of age at the parents' request. The case was similar to many others that had occurred during the preceding decade, particularly involving undertreatment of newborns with Down syndrome and spina bifida. Many of these children appeared to have excellent prospects for long, happy lives, suggesting that the decisions were not being made in the best interests of the children. In two large surveys, most pediatricians supported parental control of such decisions; some pediatricians stated that they considered their duty was not to serve the interests of their patient but rather to serve the interests of the family. These problems were compounded by the fact that decisions were often based on erroneous medical assumptions, including inappropriately pessimistic prognoses about quality of life.

As a consequence of concern about this issue in the United States, regulations were

eventually promulgated under the authority of a federal child abuse law that prohibited withholding medically beneficial treatment from disabled infants except under certain conditions. These conditions are permanent unconsciousness, "futile" treatment, and "virtually futile" treatment that imposes excessive burdens on an infant. This rule seemed to disqualify one of the most common justifications for forgoing LSMT in children—namely, the likelihood that continued biologic existence would not serve the patients' interests precisely because they would be so disabled that the burden of treatment would be greater than the benefit. One unintended consequence of this rule was an apparent shift from undertreatment to widespread overtreatment, defined as life-prolonging treatment that, in the opinion of the physician, does not serve the interests of the child. However, the regulations address state eligibility for federal child abuse funding and, absent the incorporation of similar language in state statutes, do not dictate the proper scope of medical interventions. A subsequent case involving an infant with spina bifida and other abnormalities upheld the right of a parent to decide to forgo LSMT for their child.

INSTITUTIONAL (HOSPITAL) ETHICS COMMITTEES

The controversy over forgoing LSMT of disabled newborn infants led to the formation of the "infant bioethics committee" as a pediatric forerunner of today's institutional ethics committee (IEC).

An IEC usually provides voluntary consultation, which may involve enhanced communication or conflict resolution. For the vast majority of decisions involving the medical treatment of children (including forgoing LSMT), pediatric clinicians and parents are usually in agreement about the desirability of the proposed intervention. In addition, the views of a child should be given considerable weight, especially when the burden of treatment is great and the potential benefit uncertain or remote.

An IEC typically performs at least three different functions: (1) the drafting and review of institutional policy on such issues as DNAR orders and forgoing LSMT; (2) the education of health care professionals, patients, and families about ethical issues in health care; and (3) case consultation. Although the process of case consultation may vary, ideally the IEC should adopt a collaborative approach that uncovers all the readily available and relevant facts, takes into account the feelings of those involved, and balances the vested interests, while arriving at a recommendation based on a consistent ethical analysis. These committees, or an appropriate alternative, are now required by the Joint Commission on Accreditation of Hospitals, and they often play a consultative role when parents and medical staff cannot agree on the proper course of action. They have acquired considerable influence and are increasingly recognized by state courts as an important factor in decision-making.

SCREENING AND GENETIC TESTING

Screening is the search for asymptomatic illness in a defined population; it is usually performed for the purpose of treatment but it is sometimes done for counseling or research. Several programs, such as newborn screening for inborn errors of metabolism (e.g., phenylketonuria [PKU] and hypothyroidism), are counted among the triumphs of contemporary pediatrics. The success of such programs sometimes obscures serious ethical issues that continue to arise in proposals to screen for other conditions for which the benefits, risks, and costs have not been clearly established. Advances in genetics have led to exponential growth in the number of conditions for which screening tests are available, with insufficient opportunity to study each proposed testing program.

The introduction of screening tests should be done in a carefully controlled manner that allows for the evaluation of the costs (financial, medical, and psychological) and benefits of screening, including the effectiveness of follow-up and treatment protocols. New programs should be considered experimental until the risks and benefits are demonstrated. Screening tests that identify candidates for treatment need to have demonstrated sensitivity, specificity, and high predictive value, lest individuals be falsely labeled and subject to possibly toxic treatments or to psychosocial risks. As these tests are being developed, parents should generally be given the opportunity to exercise informed consent or refusal. These safeguards have not always been systematically applied to screening programs, often resulting in serious harm to many children without compensating benefits. Familiar examples include routine fetal monitoring, which contributed to the rising rate of cesarean sections with little benefit for many infants, and the screening of premature infants for acidosis, resulting in administration of toxic amounts of sodium bicarbonate before its risks were adequately studied.

A persistent ethical issue is whether screening should be voluntary (i.e., "opt in"), routine with the ability to "opt out" or refuse, or mandatory. A voluntary approach entails an informed decision by parents before screening. Concern is often expressed that seeking informed consent is ethically inappropriate for tests of clear benefit, such as PKU screening, because refusal would constitute neglect. Routine testing with an "opt out" approach requires an explicit refusal of screening by parents who object to this intervention. The principal ethical justification for mandatory screening is the claim that society's obligation to promote child welfare through early detection and treatment of selected conditions supersedes any parental right to refuse this simple medical intervention. However, obtaining informed consent for newborn screening may allow for more prompt and efficient responses to positive results, and for incorporating experimental tests into established screening programs. Although more research is necessary, one study showed that a reasonable attempt at consent could be made on a statewide basis without excessive time or cost and without undue effects on compliance.

These same two ethical principles of demonstrated benefit justifying the risks of screening and informed consent can be applied to genetic testing for late-onset disorders. The knowledge of increased risk status may lead to lifestyle changes that can reduce morbidity and the risk of mortality, or may precipitate adverse emotional and psychological responses and discrimination. Because many adults choose not to be tested for late-onset disorders, we cannot assume that a child would want or will benefit from similar testing. Genetic testing of children and adolescents for late-onset disorders is generally inappropriate unless such testing will result in interventions that have been shown to reduce morbidity and mortality when initiated in childhood. Otherwise, such testing should be deferred until the child has the capacity to make an informed and voluntary choice.

ADOLESCENT HEALTH CARE

Many adolescents resemble adults more than they do children in their competence to consent to health care. Competence is not a global quality: teenagers may not be able to support themselves, yet they may still be competent to consent to health care. In addition to competence, there are public health reasons for allowing adolescents to consent to their own health care with regard to reproductive decisions, such as contraception, abortion, and treatment of sexually transmitted diseases. Strict requirements for parental consent may deter many adolescents from seeking health care, with serious implications for their health and other community interests.

Weighed against these arguments are the legitimate interests of parents in maintaining responsibility and authority for child rearing, including the opportunity to influence the sexual attitudes and practices of one's children. Another claim is that public support for access to such treatment, particularly contraception and abortion, implicitly endorses and encourages sexual activity, aggravating rather than ameliorating the problems. Similar concerns underlie the objection to providing sterile needles for intravenous drug abusers for the purpose of reducing the risk of acquiring hepatitis or human immunodeficiency virus. Critics complain that such programs give children the message that illegal drug use is supported by the state as long as it is done safely, even though it is now generally accepted that access to sterile needles results in a decrease in new cases of acquired immunodeficiency syndrome. The pediatrician's role and behavior in these disputes will be influenced by his or her own moral beliefs and by assessments of the competing facts and arguments. Physicians need to consider the possibility that a moralistic position may deter adolescents from seeking health care or counseling.

RESEARCH

The central ethical distinction between research and standard clinical practice is researchers' commitment to generating knowledge, perhaps to the benefit of future patients or society, in addition to their responsibility for patients who are the human subjects of the investigation. Research is defined in the federal regulations as "a systematic investigation designed to

develop or contribute to generalizable knowledge." For any research to be performed, the risks should be minimized and reasonable with respect to any anticipated benefits to the subjects and the importance of the resulting knowledge. Because children generally cannot give voluntary and informed consent to their own research participation, there are further restrictions on the research risks to which a child may be exposed. These restrictions specify the conditions under which a parent has the moral and legal authority to permit a child to participate in research.

In *nontherapeutic research*, there is no expected direct benefit for the subject; therefore, any risk may present an unfavorable risk:benefit ratio. Some argue that children, along with other nonconsenting subjects, should never be used in nontherapeutic research, as a person should never be used solely as a means to an end. The more widely held opinion is that children may be exposed to at least *minimal risks*, although the reasons for this exception are disputed. Some argue that children have a duty to contribute to the social welfare, although the federal regulations do not allow competent adults to be used as research subjects for this justification without their consent. Others argue that participation in research can provide an indirect benefit by fostering a sense of altruism or citizenship through a child's assent. The federal regulations allow healthy children to participate in minimal risk research based on an analogy to parental authority to make decisions about risk exposure in everyday life. The regulations also state that children with a condition can be exposed to slightly more than minimal risk in nontherapeutic research if the child's experience is similar to everyday life with that condition and the anticipated knowledge is of vital importance for understanding or benefiting that condition. This "minor increase over minimal risk" category is the most controversial.

Much of the controversy over nontherapeutic research stems from the wide variability in the interpretation of minimal risk. The federal regulations define minimal risks as the risks that are "ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests." Some interpret this to include procedures similar to those done in primary care office visits, but others claim that an invasive procedure such as a liver biopsy may be done if the risks, in the hands of a particular investigator, are empirically no higher than those of a routine office visit or if the procedure is routine for a visit to a specialist. When originally proposed, the definition of minimal risk referred to the life of a healthy child. The regulations omitted this phrase out of concern that research would be hindered, thus contributing to the wide range of interpretation. However, many advocate restoring the phrase "of healthy children" to the definition of minimal risk, because valuable research on a condition may still proceed under the "minor increase over minimal risk" category. As originally proposed, the concept of minimal risk serves a moral purpose in limiting a parent's authority to permit nontherapeutic research on a healthy child. To define minimal risk using only statistical considerations (such as the product of probability and magnitude) may overlook this moral purpose. The risks of each intervention or procedure in the research needs to be considered separately and balanced against any direct benefit to the subject or knowledge to be gained.

The term *therapeutic research* is misleading in that not all interventions or procedures included in a research study may offer the prospect of direct benefit to the subject. There are likely to be nontherapeutic aspects of the research, such as an extra blood test or chest radiograph. As discussed above, the nontherapeutic parts of the research need to be no more than a "minor increase over minimal risk" and cannot be justified by the anticipated benefit of other parts of the overall research study. The risks of interventions that offer direct benefit can be more than minimal. However, the risks must be justified by the anticipated benefit, and the balance of anticipated benefit to the risk should be as favorable as that presented by available alternatives. A child should not be disadvantaged by being enrolled in a research study.

Innovative therapy is defined as a new and unproven intervention done primarily for the benefit of the patient, with no intent to gather new information. Such innovations may be more hazardous and ethically more problematic than research, in part because they are not subject to peer review and because toxicity is not being systematically assessed. This kind of therapy is also subject to abuse because its

definition is a matter of intent, and thus difficult for others to disprove. Although innovative medical and surgical interventions are not subject to research regulations, some argue that clinicians have a moral obligation to submit innovative therapies to formal evaluation.

The regulations in the United States for the protection of human research subjects rest on two foundations: (1) voluntary and informed consent and (2) the independent review of the research risks. The standard for informed consent in a research setting is higher than for clinical care because the risks and benefits are typically less clear, the investigator has a conflict of interest, and humans have historically been subjected to unauthorized risks when strict requirements for consent were not respected.

Adolescents who are competent may sometimes consent to be research subjects. It is also generally acknowledged that children should be given the opportunity to *dissent*, particularly for nontherapeutic research, when there cannot be a claim that participation is in the child's interest. In the United States, national regulations require that reasonable efforts be made at least to inform children who are capable of understanding that participation is not part of their care and that, therefore, they are free to refuse to participate. In addition to the protection that informed consent is intended to provide, virtually all research involving human subjects in the United States is reviewed by an institutional review board, required by federal regulations for institutions receiving federal research funds and for Food and Drug Administration–regulated drug research. It is uncertain whether such review is legally required for research that is not federally funded or for research in settings that receive no federal funds, such as private clinics. The principles of ethical decision-making that led to the involvement of ethics committees in clinical decisions argue for similar review of research involving children, regardless of the source of funding.

A general ethical principle is that individuals who are capable of voluntary and informed consent be approached first about research participation. An unintended result is that the majority of marketed medications are not labeled for use in children. Pediatricians are left with a difficult choice of using medications “off label” and risking increased toxicity or decreased efficacy, or not using a medication and potentially denying a child an important therapeutic advance. To ameliorate this problem, the United States has granted 6 mo patent extensions for the performance of requested pediatric studies, resulting in new pediatric labeling for many important drugs. New drug applications must include studies in children unless granted a specific waiver. In addition, grants submitted to the National Institutes of Health must include children in the absence of scientific or ethical reasons to the contrary.

FETAL WELL-BEING AND TREATMENT

As our knowledge of factors influencing fetal development and well-being expands, there is increasing discussion about the proper balancing of maternal and fetal interests when a pregnant woman's behavior affects the well-being of her fetus. Interventions can now be directed primarily toward specific medical and surgical conditions of the fetus, rather than toward the general health of the pregnant woman with a secondary

impact on the fetus. As a result, questions arise about a clinician's responsibility when the interests of the pregnant woman and her fetus appear to conflict. There are two particularly controversial areas in which this question arises—the provision of fetal medical or surgical treatment and the reporting of pregnant women for drug and alcohol use.

The most dramatic of these conflicts arises when a pregnant woman refuses standard, effective treatment essential for the benefit of a fetus/infant who is at high risk of death or serious disability, such as refusal of cesarean section for placenta previa in a voluntary pregnancy near term involving a presumably normal fetus/infant. Courts in the United States have sometimes decided that a woman can be required to undergo such a procedure when the benefit to the emergent child is clear. A federal court decided that such an order was inappropriate in a case involving a 26-wk-old fetus and, by implication, other cases in which the benefit of intervention was in doubt. In general, a clinician should not oppose a pregnant woman's refusal of a recommended intervention unless (1) the risk to the pregnant woman is negligible, (2) the intervention has been shown effective, and (3) the harm to the fetus is certain, substantial, and irrevocable. When these three conditions exist, a clinician may try to persuade and, if unsuccessful, seek some other avenue of conflict resolution (such as through an IEC). Rarely, and only as a last resort, should a clinician seek judicial authorization to override a pregnant woman's dissent.

Child abuse statutes have also been invoked in attempts to modify the behavior of women who ingest alcohol or illicit drugs during pregnancy and expose the fetus/infant to harm. Pediatricians considering reporting such cases must consider the likelihood of benefit from reporting, the harm to the child as well as to the mother if criminal charges or custody changes are sought, and the possible effects that reporting may have in driving pregnant women away from the health care system, particularly from prenatal care. The US Supreme Court has held that drug testing of pregnant women without consent was in direct violation of the Fourth Amendment, which provides protection from unreasonable searches.

ACCESS TO HEALTH CARE: RATIONING (DISTRIBUTIVE JUSTICE)

The most serious ethical problem in health care in the United States may be the inequality in access to care. No other major industrial country rations basic health care on the basis of ability to pay. Comprising nearly one of every five uninsured persons, more than 9 million children and adolescents lack basic health care coverage. This lack of adequate and affordable health care has serious consequences in terms of death, disability, and suffering. The central ethical principle at stake is fair opportunity to participate in the benefits of society; preventable death and disability undermine the claim that the society is one of equal opportunity. Another aspect of the claim of unfairness is that the present system is maintained by those who are already advantaged because of financial or social status, thereby aggravating existing inequalities.

Rationing of health care can be defined as limiting access to wanted and needed services of known benefit. It is increasingly recognized that no society can provide all

beneficial services to all its citizens; rationing is therefore unavoidable. The question is not whether to ration health care services but how to do so fairly. Apart from ability to pay, other ways of rationing could be based on cost:benefit analysis, age, or likely effects on quality of life. Even universal systems of health care coverage effectively ration through limited availability, with the option of purchasing additional desired services using private resources. Some argue that such a multitiered system is fair as long as the basic health care package is appropriately defined and sufficiently funded.

Chapter 3 - Cultural Issues in Pediatric Care

Jill E. Korbin

Considering the worldwide diversity of cultures, the diversity of cultures in the United States, and the diversity within any culture, no pediatrician can be expected to be an expert on all cultures that he or she might encounter. What can be expected of the pediatrician, however, is expertise in a set of issues related to understanding how culture impacts the quality of pediatric care and health outcomes. This chapter is directed at facilitating understanding of this complex interaction between culture and pediatric practice.

Culture and ethnicity are relevant to culturally competent clinical care of children and to understanding children and the experience of childhood as relevant to health. The National Academy of Sciences' evaluation of the “current science of early childhood development” made culture the second of 10 core concepts: “Culture influences every aspect of human development and is reflected in childrearing beliefs and practices designed to promote healthy adaptation.” However, the complexity of culture and ethnicity in relation to health leaves many questions unanswered.

Current demographic trends in the United States demand a high standard of culturally informed, or culturally competent, health care. As projected, European-Americans will not retain their majority status, and the minority-majority transition will occur at an earlier date for children. Pediatricians can expect to see greater percentages of diverse populations in their practice and research. Demographic trends take on even more importance in pediatric care when coupled with the growing body of evidence on cultural and ethnic disparities in health resulting from a combination of lifestyle issues influenced by socioeconomic disadvantage, biologic and genetic factors, and access to and use of health care. Culture and ethnicity potentially affect all of these matters. Among the most compelling reasons for the tie of culture and ethnicity to pediatrics is that pediatrics, like no other branch of medicine, has the opportunity to shape an individual's lifelong perceptions of health care and use of health services. In addition to enhancing individual health, there is the potential for influence on the health of populations. Children are often at the forefront of societal and cultural change related to health and well-being, such as public health campaigns for smoking cessation and seatbelt use.

CULTURE AND ETHNICITY

Many definitions of culture center on the ideas of culture as a learned, shared, and interpretive force that guides interactions among people. Culture is a broader term encompassing ethnicity. Children are not passive recipients of socialization into their culture, rather they shape and reinterpret it. Culture is experienced variably by different members of a group; it is not static, but dynamic and constantly changing. *Ethnicity*, which is generally used by lay people synonymously with *culture*, refers to group membership by virtue of common ancestry. This membership can be self- or other-identified. The terms *culture, ethnicity*, and *race* should not be used interchangeably or synonymously, and care should be taken not to confound culture and ethnicity with religion or socioeconomic class.

The relationship of culture and ethnicity to health care, including pediatrics, has been obscured by the use of major census categories to designate groupings of people, such as Latin-American/Hispanic, Asian/Pacific Islander, Native American, and African-American. There are many distinct groups found within the census categories. The designation European-American similarly encompasses a wide range of cultures and ethnicities. These categories, which have found their way into common parlance, do not reflect cultural reality and may, in fact, mask rather than illuminate culture. At best, these categories can be used as shorthand or a starting point. Geographic considerations also are less frequently noted, such that Puerto Ricans, for example, living in New York may be quite different from Puerto Ricans living in Cleveland. Variability within any cultural or ethnic group often exceeds that between groups, and populations continually adapt to changing circumstances. Furthermore, when culture or ethnicity is identified on the basis of phenotypic characteristics, such as skin color, such groupings may not be meaningful designations of culture or ethnicity, but instead serve as proxies for socioeconomic status.

Both culture and medicine are dynamic and constantly changing. For example, in recent years the extensive use of nonconventional and alternative remedies by the American public, including children, has been recognized (see Chapter 713). The use of complementary and alternative medicine occurs in educated and affluent groups, challenging conventional wisdom that such practices are limited to those culturally different from the dominant society. Such complementary and alternative practices are included in many medical school curriculums.

CULTURAL COMPETENCE AND PEDIATRIC PRACTICE

Cultural “competence” refers to the acquisition of knowledge and skills needed to transcend cultural boundaries; it moves beyond “sensitivity” and “awareness.” The need for cultural competence is most obvious among patients who, for example, wear traditional dress or speak another language. In these circumstances, cultural diversity is relatively easy to spot, even if the possible health effects are not always straightforward. On the other hand, even if a patient appears to be culturally similar to the physician, congruence in health beliefs and behaviors cannot be assumed. What might be assumed to be similarities in orientation do not necessarily ensure optimal care, even among physicians. Whereas physicians' children have been found to have better access to pediatricians and increased pediatrician visits if hospitalized, they also experience delays in seeking pediatric care. Furthermore, pediatricians have been found to provide less detailed medical instructions and to be reluctant to discuss children's behavioral problems with fellow physicians than with other parents.

One strategy for achieving cultural competence is to conceptualize illness as a series of unfolding stages. The pediatric visit may not be the first stage but usually comes later in the process after symptom recognition, formulation of etiologic explanations, and lay referral and consultation. Knowledge about each stage obtained during a pediatric visit can diminish the likelihood of cultural conflict or resolve it more quickly if it occurs. In eliciting a narrative account of illness while obtaining a medical history, information on culture can be obtained without adding a burdensome time commitment. Two points in the unfolding process are used here as illustrations: symptom definition and etiologic explanations.

An initial point in an illness episode is the identification of symptoms of ill health. Children may identify these on their own, or they may be identified by a parent or caregiver. Whether or not culturally diverse children, parents or caregivers, and physicians converge on the significance of symptoms is important to the course of subsequent treatment. Folk diagnoses and medical diagnoses may appear divergent, even when they converge in important ways. For example, a Mexican mother's diagnosis of entities such as *susto* (fright sickness), *mal de ojo* (evil eye), or *caida de mollera* (fallen fontanel) may be regarded as being at odds with the physician's diagnosis. Mothers may regard these entities as untreatable by Western physicians, and physicians might dismiss these folk classifications in their diagnosis. However, even though the labels for these conditions and their etiologic attributions differ, the presenting symptoms are likely to be recognized by both parent and physician as significant and potentially life-threatening, thereby establishing more common ground than at first is apparent. Common ground, then, can be found in the seriousness of symptoms, such as fever. Once symptoms are identified as signs of ill health, a process begins to try to explain their cause. Cultural conflict in medical care often emanates from disagreement as to etiology, because discerning the cause is important in formulating the cure. Although there is both intracultural and intercultural variability, there may be more congruence across cultures than was previously thought. Middle-class European-Americans and Latin-Americans, for example, recognize the common cold as a biomedical entity but also attribute its etiology, at least in part, to becoming chilled as part of a hot-cold system of beliefs. Nevertheless, the differences in culture may interfere with care if a pediatrician's planned course of treatment is not presented as related to the family's attribution of the cause of illness.

Cultural knowledge is also empirical knowledge. For example, because remedies have worked in the past, it is assumed that they will work in the future. Middle-class parents in the United States routinely accept a pediatrician prescription for a second course of antibiotics for otitis media if a child's symptoms persist, assuming not that antibiotics are useless, but that a different drug or a longer course of treatment will resolve the problem. The same is true for indigenous treatments that have been proven through the force of custom over time.

EMERGING AREAS IN CULTURE AND PEDIATRICS

One area of interest, termed *evolutionary medicine* or *ethnopediatrics*, looks at cross-cultural variability in child care practices and seeks to understand these practices in the context of human evolution. Sleep problems, a common issue in pediatric practice, serve as an example. Co-sleeping with infants has likely occurred throughout human history, is exceedingly common cross-culturally, and is more common in the United States than was previously thought. While recent years have seen increasing flexibility in pediatric advice in this domain, common pediatric guidance is still that infants and young children should sleep separately from their parents, in a different room, and in their own beds for the night. Some sleep problems, then, may be viewed as rooted in behaviors of child care that may be inconsistent with the biologic needs and capacities of human infants rather than a failure on the part of the parent, child, or both.

Another emerging area is viewing children as active shapers of their social and cultural environment rather than passive recipients of socialization. Even though pediatricians have

always relied on children for information, the social sciences are now more supportive of children's viewpoints being included in decisions regarding their lives. The United Nations Convention on the Rights of the Child also includes provisions affirming this position.

A third area involves capitalizing on cultural and ethnic strengths and looking for common ground. Culture and ethnicity have more often been approached as being potential sources of conflict with the health care system rather than recognizing the point of congruence.

Chapter 4 - Child Health in the Developing World

Kristine Torjesen
Karen Olness

Ninety percent of children in the early 21st century are born into the developing or third world. This chapter reviews the demographics, the health problems of children in the developing world, the larger ramifications of their health problems, the skills needed by individuals and institutions who help them, and future challenges. Fifty years ago, child health leaders such as David Morley and Cicely Williams emphasized the special needs and problems of children in the developing world. Huge population increases in the developing world now mean that there are many more children suffering from the same problems identified by Morley and Williams.

DEMOGRAPHICS

According to current UNICEF data, there are 71 million children younger than 18 yr in the United States and 2.1 billion children younger than 18 yr in the rest of the world. The mortality rate of children younger than 5 yr is 8/1,000 in the United States and 86/1,000 for the overall child population of the world. One thousand infants die each hour; 970 of these deaths occur in developing countries. In addition, human potential is unrealized because of poor health, especially cognitive impairment caused by health problems, with negative effects on individuals, families, communities, and countries in terms of productivity, economics, and politics. Population projections to 2025 show continuing rapid growth in Africa, Western Asia, South Central Asia, Southeast Asia, West Asia, South America, and Latin America, with modest or slowing growth rates in East Asia, North America, and Europe. Hundreds of thousands of children born in developing countries move into Europe and into North America as refugees, immigrants, or international adoptees. Dr. Robert Haggerty wrote, “Pediatric practice in the next millennium will require greater knowledge of new morbidities…Diversity in ethnic and cultural backgrounds and beliefs will continue to increase, and will need to be understood to prevent and treat diseases of children effectively.”

HEALTH PROBLEMS OF CHILDREN IN THE DEVELOPING WORLD

According to the World Health Organization (WHO), 10.5 million children younger than 5 yr died in 1999. Of these, 99% lived in developing countries. Causes of death were attributed to malnutrition (54%), perinatal conditions (20%), pneumonia (19%), diarrhea (15%), measles (8%), malaria (7%), HIV/AIDS (3%), and other (28%). One third of births in the developing world are not registered. Malnutrition among pregnant women leads to stunting of an estimated 182 million children. From 1990 to 2000, at least 20 million were children displaced by disasters at any given time. In 2000, more than 10 million children younger than 15 yr had lost one or both parents to AIDS. There is an increasing number of street children in the world; many suffer infectious diseases such as hepatitis and tuberculosis. In much of the developing world, there are no resources for poor children with conditions such as leukemia, brain tumors, AIDS, head injuries, congenital heart disease, or metabolic disorders.

Between 1980 and 2000, there were dramatic increases in the percentage of children immunized in developing countries and, as a result, diseases such as poliomyelitis and measles are much less common. However, immunizations for diseases such as hepatitis, haemophilus influenza b, and varicella are rarely available in the developing world. The number of children infected with HIV has increased dramatically, as has the number of children suffering from malnutrition associated with disasters. Malaria and tuberculosis also affect greater numbers of children than they did a decade ago. Malaria is the leading cause of hospitalization, mortality, and morbidity in children younger than 5 yr who live in sub-Saharan Africa. Malnutrition, including both calorie and micronutrient deprivation, causes acute and chronic morbidity, contributes to reduced immunity, and increases the likelihood of mortality and morbidity in association with infectious diseases.

IMPAIRED LEARNING

Approximately one third of children younger than 15 yr in developing countries either have or are at risk for impaired learning. Major hazards to early brain development include malnutrition, infectious diseases (e.g., meningitis), prematurity and newborn asphyxia, in utero exposure to alcohol and drugs, lead poisoning, genetic disorders, head injuries, and institutionalization. Malnutrition experienced during the critical periods of brain development from the second trimester of pregnancy until 2 yr of age is most likely to be associated with subsequent cognitive impairment. Galler and others have documented that a few months of malnutrition in the first year of life is associated with learning disabilities, attentional problems, and reduced school performance in 65–70% of children. Iron deficiency, very common among infants in the developing world, is associated with continuing learning problems a decade later. Iodine deficiency is also common, especially in large areas of China, Central Africa, and South America, and is associated with mental impairment in children. Further research indicates that cognitive impairment due to early brain insults may not be apparent until the child is well along in school. Children seem to do fairly well in the early school years but begin to manifest executive dysfunction in middle school years when more goal setting, planning, organizing, and time management are required. Children with learning impairments, especially those without access to special

education or training, are likely to drop out of school and to have difficulties finding and maintaining employment, and they are less likely to be contributing citizens in their communities (see Chapter 39).

CHILDREN AND DISASTERS

Most disasters occur in developing countries and are due to natural events such as hurricanes, industrial accidents such as the 1984 chemical disasters in Bhopal, or wars with associated displacement of populations, more than half of whom are children. The number of complex humanitarian emergencies has increased during the past decade. Children involved in such disasters are at risk for infectious diseases, malnutrition, and psychological trauma, which may be lifelong. Children displaced from Southeast Asia, Central Africa, and Bosnia by war have a high prevalence of mental health problems continuing years after resettlement.

INSTITUTIONALIZATION

The number of children institutionalized in developing countries is unknown, but the number of institutions for orphan children has increased in countries of the former Union of Soviet Socialist Republics, Eastern Europe, sub-Saharan Africa, India, and China in the past decade. Reasons include death of parents from AIDS, poverty in families who might ordinarily adopt child relatives, political upheavals, and community chaos. A small percentage of the institutionalized children are adopted by North American or European families. Eighteen thousand children from abroad are adopted into American families each year (see Chapter 30). About half of children adopted from orphanages abroad are malnourished. Rickets is common, as are intestinal parasites. Many children have been infected with tuberculosis, hepatitis B, hepatitis C, or syphilis. Of great concern are the frequent developmental delays and attachment problems, which increase after the first year of life of these orphan children.

APPROACH TO CHILD HEALTH IN THE DEVELOPING WORLD

Traditionally, efforts to improve child health in the developing world have focused on primary health care. This approach concentrates on improving public health and basic health care at the community level, usually by training village health workers to recognize and manage childhood illnesses such as diarrhea and pneumonia. The primary health care approach is essential in developing countries, where access to basic medical facilities and trained health care professionals is often lacking and where the majority of childhood diseases are preventable. However, the primary health care approach includes teaching village health workers to recognize and refer sick patients to acute health care facilities. Currently, there are inadequate resources devoted to training health professionals and establishing such referral centers in most developing countries; they often do not exist and, therefore, sicker children suffer or die. Depending on the resources available and the socioeconomic situation of a given country, these outcomes may be unavoidable. However, as the public health infrastructure improves in a developing country, it becomes increasingly important to train local child health specialists. These child health specialists provide referral care to individual children and serve as the backbone for long-term improvements in child health by providing local expertise and knowledge for the formulation of child health policy in their own countries.

Pediatricians and child health professionals can contribute to improving both primary health care and higher levels of medical care for children in developing countries. The field of pediatrics has excelled at integrating primary health care and preventive care into the practice of curative medicine (Chapter 5). Pediatricians have long recognized the need to provide comprehensive care to children and to use any point of contact as an opportunity to assess the overall health of the child and family. These principles are being implemented by WHO on a global level through the program Integrated Management of Childhood Illness (IMCI). In the past, many health programs in developing countries took a single-condition approach (sometimes called a vertical approach), for example, achieving specific immunization goals or eradicating malaria. This very focused approach fails to adequately address the health care needs of children. A visit to the vaccine clinic that does not address a child's malnutrition or diarrhea is a lost opportunity to prevent illness and promote health for that child. IMCI is a positive step toward providing higher-quality, comprehensive care for children in the developing world. The IMCI health care algorithms are written at or slightly above the level of a village health worker, and they target children younger than 5 yr old, the group with the highest death rate from common childhood diseases. However, the broader guideline of integrating curative and preventive care for children is appropriate at all levels of health care provision. For infants 1?wk to 2?mo old, IMCI has as its clinical priorities the assessment of the main signs and symptoms of bacterial infection, diarrhea, feeding problems, low weight, and immunization status. For children 2?mo to 5 yr old, the IMCI priorities of management emphasize cough and breathing difficulties, diarrhea, fever, ear problems, nutritional status, and immunizations.

In most settings, it is difficult to separate the health of the child from that of the family and the broader social context in which the child lives. This is particularly true in the developing world. Maternal health practices strongly impact child health, particularly in the perinatal period. Prenatal care, neonatal resuscitation, maternal nutrition, breast-feeding and weaning practices, and maternal depression all may have profound effects on a child's well-being. Economic conditions and family resources drive health care decision-making. For example, do we pay for our sick child's medication or buy food for our other children? Environmental conditions limit the effective treatment of preventable illnesses, such as diarrhea and malaria. Political instability and violence interfere with the establishment and maintenance of health care systems. Cultural and religious practices may limit or counteract the effectiveness of medical therapies. Child rights abuses may underlie presenting illnesses. Much of the childhood disease burden in developing countries may rightfully be seen as the medical manifestations of social illnesses, such as lack of education, poverty, and other forms of injustice.

HOW CHILD HEALTH PROFESSIONALS CAN HELP THE CHILDREN OF THE WORLD

Depending on their areas of skill and interest, child health professionals can provide service, research, and education in developing countries. The first step is to educate oneself about child health problems in developing countries. Skills are needed for a child health specialist to provide services in developing countries. The concrete skills that improve the likelihood of making a positive contribution toward addressing child health care issues in the developing world include training in pediatrics, public health, epidemiology, infectious diseases, nutrition, and immunizations. Clinical and community outreach experience, even if in an industrialized setting, is also useful. All child health professionals should take training in disaster management and be prepared to help colleagues in their own countries, as well as in other countries, in

case of natural disaster, war, or bioterrorism (Chapter 706). There is a great need during disasters for assistance provided by those who understand the special needs and issues of children. Language skills are important, as is prior experience with different cultures and belief systems. Many of the skills required to help children in the developing world are

more abstract in nature: flexibility, tolerance for the unexpected, respect for local colleagues and their practice of medicine, ability to function with different and perhaps frustrating cultural norms and communication styles, and ability to triage when faced with limited resources. A particularly difficult dilemma for child health providers in developing countries is balancing the very pressing curative medical needs of children with their more long-term preventive care needs. Children require clean water, food, shelter, warmth, and love to grow healthy; they also need medical treatment for acute illnesses. When faced with limited resources, inadequate public health infrastructure, and many sick children, the individual practitioner can be overwhelmed by a myriad of tasks. With experience, most practitioners in the developing world find a way to prioritize the conflicting and compelling needs before them.

Pediatric research in developing countries has lagged behind that in Western countries. As a result, there is a lack of knowledge in many areas, including, for example, the long-term effects of medications used to treat many parasitic infections, the interactions between traditional herbal therapies and antibiotics, the extent of genetic diseases, the prevalence of iron deficiency, and the neurodevelopmental effects of cerebral malaria. It is appropriate for child health specialists and institutions from wealthier nations to assist colleagues in developing countries to develop research skills, design appropriate projects, find financial support, and implement the research project. The same rules for protection of human subjects should apply everywhere, and it is important that child health researchers assist colleagues in developing countries to develop and use institutional review boards (Chapter 2). Research projects in developing countries should be designed primarily for the benefit of the people in those countries, although information derived may prove to be useful throughout the world. Training child health colleagues in research skills is likely to result in long-term benefits for educational institutions, for trainees, and for children.

For those who cannot donate time and effort, individual financial contributions can be helpful in supporting child health programs managed by others. Child health specialists from wealthier communities can provide education materials, supplies, equipment, and psychological support to colleagues in developing countries. Reciprocal visits and continuing medical education opportunities can be beneficial to both communities. It is important to spend time working with colleagues in the actual setting where any teaching and resources will be applied in order to know what is needed and appropriate for that setting. Building upon personal relationships and contacts can lead to individual efforts to improve child health, or it may open doors for larger collaborations. Developing sister relationships between the pediatric practices of two communities can provide an excellent context for two-way learning experience and for sharing of resources.

FUTURE CHALLENGES

The 1990 United Nations World Summit for Children recommended a 10 year program to achieve basic health and social goals for children. With the exception of the immunization goals, they were not met. The participants could not have anticipated the increased number of children with HIV infection, the increased numbers of disasters, the continuing political upheavals, and burgeoning population numbers. It is important that child health professionals do their best for individual child patients and also participate in the broader public health and community planning on behalf of children. Probably the highest priority for the world should be the prevention of childhood learning problems. Health and human service professionals around the world must foster a global awareness about the impact of early events on the developing brain of a child, on his or her life, on the community, and on the world.

Chapter 5 - Preventive Pediatrics

Theodore C. Sectish

Prevention in the health care of infants, children, and adolescents is at the core of the field of pediatrics. During the 20th century, the lifespan of people living in the United States increased by more than 30 yr. Many of the public health measures that contributed to this increased lifespan were aimed at pediatric populations and represent some of the most significant achievements of preventive pediatrics during that century. Key examples include vaccination programs, motor vehicle safety measures, control of infectious diseases, safer and healthier foods, healthier mothers and babies, family planning, fluoridation of drinking water, and recognition of the hazards of tobacco use. Pediatricians have led the way in these and many other scientific, public health, and public policy efforts to address issues that affect populations of children through their professional activities as educators, advocates, scientists, and experts in child health.

At the level of individual patients, pediatricians practice preventive pediatrics with their clinical activities in health supervision. Preventive pediatrics in practice is the focus of this chapter and encompasses (1) health supervision of infants, children, and adolescents, (2) topics of frequent concern during health supervision visits, and (3) unmet needs and future challenges in preventive pediatrics.

HEALTH SUPERVISION OF INFANTS, CHILDREN, AND ADOLESCENTS

Pediatricians have a unique opportunity to improve the lives of children by making effective use of health supervision visits. Guidelines for health supervision address continuing and new morbidities facing children and families. These morbidities include childhood injuries, educational failure, child abuse and neglect, family violence, parental health issues, teenage pregnancy, environmental health concerns, media influences, obesity, and risk-taking behaviors such as the use of tobacco, alcohol, and drugs. Within health supervision visits, pediatricians should assess cognitive development, social competence, and family life in addition to performing traditional well child visits. The effectiveness of health supervision visits depends on the partnership that pediatricians develop with children and families to promote a collaborative effort toward achieving optimal health.

PRINCIPLES OF HEALTH SUPERVISION

Health Promotion.

Health is not merely the absence of disease, but includes many dimensions of well-being including physical,

mental, social, environmental, and personal. Promoting health requires pediatricians to acknowledge the complex forces that impact health, such as familial, socioeconomic, educational, developmental, and biologic entities. With these complexities in mind, pediatricians tailor health supervision visits to individual children to provide optimal care and promote health.

Partnership.

Partnership in health supervision requires an appreciation of the context of each child and family. Children have many unique attributes based on the diversity of family structure, culture, ethnicity, language, socioeconomic status, special health care needs, and educational background. Practitioners who partner with children and families by communication and understanding, educating families about health concerns, acknowledging their strengths, and acquiring their trust may enlist children and families in the process of health supervision. This facilitates early detection of disease during intervals between regularly scheduled visits. Collaboration enables families to establish goals, share responsibility for health care, and develop self-esteem, confidence, and competence.

Communication.

(See Chapter 17.1 .) Effective communication is at the heart of establishing a therapeutic relationship. In health supervision visits, the roles of pediatricians are expanded beyond diagnosticians to those of healers, educators, and counselors. Effective communication skills include (1) demonstrating respect and empathy for children and families, (2) listening actively to concerns and conveying understanding, (3) using nonjudgmental, open-ended questions to promote dialogue, (4) offering supportive comments to foster self-esteem and confidence, and (5) establishing relationships with children by communicating with them directly.

Continuity and Coordination of Care.

Pediatricians spend 25–40% of their time performing health supervision visits throughout infancy, childhood, and adolescence. Although these visits are brief encounters in the lives of children and families, significant relationships are built over time. It is the longitudinal nature of health supervision that allows these brief encounters to have a lasting impact. For children whose lives are affected by chronic conditions, continuity and coordination of care are especially essential to their health care needs (see Chapter 37). The pediatrician should coordinate care, communicate with specialists, collaborate with family and community resources, and co-manage children with chronic illness with subspecialty colleagues. The accessibility of pediatricians in the community and their availability for day-to-day problems promote these important roles. In this context, health supervision evolves into management of chronic conditions, providing patients with a *medical home*

PERIODIC HEALTH SUPERVISION VISITS

The suggested sequence of health supervision visits is listed in Table 5–1 . Beyond history and physical examination, screening, and immunizations, health supervision visits should include surveillance of developmental milestones, observations of parent-child interaction, anticipatory guidance and counseling, and an opportunity to address concerns and questions of children and families. Table 5–2 provides a list of essential elements for health supervision visits at specific ages.

Time devoted to health supervision visits has increased over the last several decades, based in part on the increasing number of potential topics that need to be explored with children and families. To be more time-efficient and ensure complete documentation, pediatricians should consider using *structured encounter forms* or conducting *group well child visits*. Structured encounter forms may improve the delivery of health information, increase parental satisfaction with quality of care, and improve documentation and efficiency. Preprinted forms and downloadable forms from the Internet are available and should be reviewed and adapted for an individual practice setting. *Group well child visits* are effective alternatives or complementary

TABLE 5-1 -- **Suggested Schedule of Health Supervision Visits**

Infancy 0–1 yr	Early Childhood 1–4 yr	Middle Childhood 5–10 yr	Adolescence 11–21 yr
Prenatal	15 mo	5 yr	11 yr
Neonatal	18 mo	6 yr	12 yr

12 mo			19 yr
			20 yr
			21 yr

to individual well child visits. Typically, groups of infants and children of similar ages and their families participate in sessions lasting 45–60?min led by primary care pediatric providers. By allowing ample time for discussion about child-rearing issues, group well child visits promote observations of parent-child interactions, facilitate

education and interchange, and serve as support groups. Group well child visits for families with infants may improve parental knowledge of parenting and child development, whereas families with adolescents may benefit from sessions that address issues of smoking, drinking alcohol, or nutrition and allow parents to share parenting experiences.

TOPICS OF FREQUENT CONCERN DURING HEALTH SUPERVISION VISITS

In the course of well child visits, pediatricians often provide advice in areas of behavior and parenting and educate families about common issues in growth and development. Information, education, and support provided during health supervision enable parents to feel successful in their roles. Clinics and offices serve as clearinghouses of information by providing patient education materials, such as handouts, brochures, and references, and by training office staff to educate patients and families on the telephone, in the clinic, or in group well child visits. As increasing numbers of families connect to the Internet, pediatricians should be involved in the development, editing, and updating of patient education information and refer families to useful websites like the American Academy of Pediatrics website, *http://www.aap.org*, which provides access to materials and resources. The following topics of parenting and child care, chosen because of their prominence in health supervision visits, are discussed with an emphasis on prevention.

Teething.

Most infants have their first teeth erupt at age 6–8 mo of age (Chapter 288). Despite the commonly held parental and professional beliefs about symptoms attributable to teething, there is no evidence to suggest an association of teething with any of the following: fever, mood disturbances, appearance of illness, sleep disturbance, drooling, diarrhea, strong urine, red cheeks, rashes, or flushing of the face or body. During the period of tooth eruption, there are numerous other events that are likely to occur coincidentally, such as the sudden onset of a respiratory or gastrointestinal illness, roseola, or gingivostomatitis. Drooling and sleep disturbances are also common at the time of tooth eruption. Parents should be given advice about common infections and symptoms, normal behaviors, and the lack of association of any of the aforementioned symptoms with teething.

Sleep Problems.

Difficulties with transitions to sleep and frequent night awakening are commonly reported in the first year of life. Separation anxiety, which develops in the latter half of the first year of life, is related to difficulty with nighttime settling and night awakening (Chapter 20.5). Pediatricians should educate parents about normal sleep requirements to facilitate their understanding of a child's need for naps, age-related sleep

* *These suggestions are an abstract of recommendations made by the American Academy of Pediatrics and Bright Futures. They are not intended to be all inclusive but rather serve as reminders of important preventive and health promotion activities that should be considered at specific ages when physician-patient encounters may occur. The content and timing of visits may be altered according to special needs and presence of risk factors. Screening requires a knowledge of specific risk factors for decisions at various age-based visits.*

schedules, and regular bedtimes (see Chapter 10). Up to 20% of older infants and children may experience sleep disturbances that include nightmares, restless legs, noisy breathing, or parasomnias such as night terrors, night walking, night talking, or bed-wetting (see Chapter 20.5).

To help a child settle at night, parents should establish a regular bedtime routine starting with a quiet interaction like reading a bedtime story. Transitional objects, such as blankets and teddy bears, are integral elements of bedtime routines and facilitate settling (falling asleep). It is important to allow infants to settle on their own, so that they accomplish a successful independent transition to sleep. If a child protests, parents should use the same consistent approach repeatedly. When parents experience difficulty with a *child who wakes at night*, a similar approach of promoting nighttime settling should be used. It is important to recognize that arousal (awakening from sleep) is a normal phenomenon and hunger is not a common cause for night awakening unless the child has been trained to feed at night (trained nighttime feeder). Parents should delay their response at first so that normal arousal states during sleep do not progress to complete awakening. When parents must respond, they should employ the same approach as they do in their normal bedtime routines.

Nightmares are common in childhood and usually involve vivid, scary, or exciting events, which are easily recalled by children upon awakening. *Night terrors* are less common events lasting 10–15 minutes in duration, during which time the child is not easily aroused and may appear frightened and agitated. On awakening, children who experience night terrors have amnesia, one of the diagnostic features. In advising parents about nightmares and night terrors, it is important to emphasize a calm and soothing approach to relax the child and facilitate settling.

Toilet Training.

In the United States, the average age of successful toilet training appears to be increasing: In the 1960s, the mean age was 27–28 mo; in the 1990s, the mean age is 35–39 mo. Causes for this increase are not entirely clear. Factors associated with successful toilet training are older parental age, nonwhite race, female gender, and single parenthood. Early training (before age 2 yr), because of its association with chronic stool retention and encopresis, should be discouraged. A key factor for parents to recognize in successful toilet training is readiness of the child. Readiness is present if a child communicates to his parents before the passage of urine or stool and can withhold elimination for a brief period of time. The process of toilet training includes positive reinforcement and regular toilet times. Minor hurdles in the toilet training process, such as fear of sitting on the toilet or accidents when not wearing

diapers, should be met with calm and understanding support.

Temper Tantrums.

Temper tantrums are a normal part of child development. However, when children express anger in outbursts of rage it is a significant challenge for parents. Parents may blame their ineffective parenting skills when the problem may relate to individual personality styles of children or triggering situations. Characterizing the type of temper tantrum may help parents to understand, so that they may apply different approaches. Types of temper tantrums include frustration or fatigue-related, attention-seeking or demanding, refusal, disruptive, potentially harmful, or ragelike. If children experience temper tantrums related to excessive fatigue or hunger, the most appropriate response should be to give support, sleep, or food. Positive remarks made at the time of the tantrum may help mitigate feelings of frustration. When a child is insistent and makes unreasonable demands, it is best to ignore him or her and allow time for the child to regain composure. Tantrums manifest by refusal to go to bed or to school should be approached with firmness and consistency. Parents should be clear and consistent in their requests for compliance but they must allow sufficient opportunity and time for children to respond. If this approach fails, it may be necessary to intervene with physical restraint by moving the child into the bedroom or the automobile. When behavior is disruptive, out of control, and occurring in a public place, such as the grocery store or a parking lot, it is necessary to remove the child from the situation and impose a time-out. A rule of thumb for the length of time-out is approximately 1?min per year of age. When significant rage with the potential for physical injury occurs, the best intervention is holding and physically restraining the child to allow time for the child to become calm and relaxed. Even though temper tantrums are a normal part of childhood and parenting, it is important to assess families to determine if there are contributing factors such as parental depression or family violence that may require other referrals or interventions.

Discipline.

This common aspect of parenting is one of the most controversial. Families often have little knowledge about effective techniques of modifying child behavior. Parents have a tendency to apply discipline strategies similar to those used by their parents. Primary care practitioners should inquire about methods of discipline and offer practical advice and alternatives. Well child visits provide observations that may serve as stepping-off points to a discussion about behavior and discipline. The basis of all effective discipline is a positive, supportive, loving parent-child relationship. Key elements include positive role modeling, praise, paying attention and listening to children, and devoting special time to enhance parent-child relationships. Pediatricians should instruct parents to maintain a positive atmosphere within their home and provide clear expectations about desired behaviors. Consistency of parental behavior, open communication within families, and mutual respect form the cornerstones for effective discipline. If there is evidence of marital discord, family dysfunction, substance or alcohol abuse, or family violence, a referral for counseling is the most important priority.

Time-out or removal of privileges should be distinguished from *punishment. Time-out* involves the removal of positive reinforcement for unacceptable behavior; this technique requires consistency and patience because its effect on behavioral change takes longer to achieve a desired result. Often time-out provokes a reactive emotional response or a tantrum. Parents should remain calm and impassive to avoid prolonging the incident or escalating the level of response. This form of discipline, among the most reliable and enduring in changing child behavior, requires parents to manage their own distress in order to be successful. *Punishment* involves issuing a negative stimulus or verbal reprimand, or inflicting physical pain, to reduce or eliminate an undesired behavior. Behavioral research on corporal punishment is inconclusive and conflicting about the long-term impact of spanking on subsequent behaviors such as antisocial actions and aggression. Clearly, physical punishment may be harsh or abusive. Although verbal reprimands may have marginal short-term benefit by interrupting or eliminating unwanted behaviors, they may interfere with the effectiveness of time-outs when used together. Verbal reprimands may become abusive when reprimands do not address undesired behaviors, but rather assault the character of the child.

Pediatricians must remain empathic, flexible, and committed to their relationship with families so that their roles as educators and child advocates may be fulfilled. Building on the relationship fostered by primary care, pediatricians have an opportunity to guide and educate families through the challenges of parenting and enable them to be successful in their parental roles. Moreover, as future research in behavioral and social science yields insight into the underpinnings of family violence, child abuse, and violence in our society, the application of this research may result in preventive interventions in well child care and recommendations for guiding parents in disciplining their children.

UNMET NEEDS AND FUTURE CHALLENGES IN PREVENTIVE PEDIATRICS

The future of preventive pediatrics will include new immunizations to prevent infections, improved screening tests to provide

early diagnosis of disease, unique genetic information to individualize preventive and therapeutic strategies, and enhanced treatments that minimize the impact of chronic conditions on the health of children. The major causes of morbidity and mortality in children, however, will continue to be related to human behavior, society, and the environment (Chapters 4 , 34 , 50 , and Part XXXII). The challenge for pediatricians in practicing preventive pediatrics is to address these threats to the health of children with new approaches to preventive pediatrics. The following topics deserve a place in preventive pediatrics and within health supervision visits.

Tobacco Use.

There are 6,000 new young smokers in the United States every day, and the number is rising. Eighty percent of people who smoke had their first cigarette before 18 yr of age. Cigarette smoking is the most preventable cause of mortality and morbidity in the United States today. Pediatricians should become active in all aspects of this public health problem, including health supervision visits. From the time of first meeting a family, especially at the birth of a baby, it is vital to obtain a smoking history and, if necessary, to provide a quit-smoking message. This preventive strategy directed at individual family members who smoke benefits children who will

be exposed to passive smoke, which has been shown to increase rates of wheezing and diminish lung function. Parental disapproval of smoking may prevent adolescents from becoming established smokers. Brief educational messages that effectively explain the relationship of smoking to lung cancer, ischemic heart disease, and low birthweight can promote smoking cessation.

Violence.

Violence permeates the lives of children (see Chapter 34). Homicide, suicide, child abuse, domestic violence, access to firearms, substance abuse, school shootings, gang participation, media violence, date rape, bullying, and terrorist acts are examples of the daily infiltration of violence into the lives of children. One study demonstrated the pervasive societal effects of violence, finding a relationship between boyhood exposure to physical abuse, sexual abuse, or a battered mother and a significantly increased risk for his later involvement in a teen pregnancy. Pediatricians should assume a clinical role in educating children and families, identifying risk factors, and making referrals for needed services and an advocacy role at the local, regional, and national level in addressing the many issues involved in this complex societal health problem.

Obesity.

Childhood obesity is an epidemic in the United States and an important topic for pediatricians to address (also see Chapter 43). Rates of type II diabetes in children have increased significantly and are related to the obesity epidemic (Chapter 583). Growth charts available from the Centers for Disease Control and Prevention(CDC) website at *http://www.cdc.gov/growthcharts/* provide pediatricians with up-to-date information regarding height, weight, head circumference, weight for height, and body mass index (BMI). See Chapter 15 . Definitions of overweight (BMI at 85th–95th percentile) and obesity (>95th percentile) are established. In the future, we may be better at predicting which obese children are at greatest risk for long-term side effects based on family history, persistence and severity of obesity, and knowing when to intervene. Pediatricians should use the CDC growth charts to monitor growth status of children. It is recommended that pediatricians calculate and monitor BMI starting at age 2 yr for all children. BMI is very useful in calculating obesity and monitoring growth trends in overweight children and those children who are concerned with their body image.

Media Influences on Behavior.

There is growing evidence that demonstrates the impact of media, particularly television, on the health of children. There are untoward effects in terms of violence and aggressive behavior, substance use, sexual activity, body image, school performance, and obesity. This influence is related to content and total viewing time. Within health supervision visits, pediatricians have the opportunity to educate parents and children about these impacts and should recommend limiting television viewing time (and video game time) to 1–2?hr per day and screening its content. Within communities or at the national level, pediatricians may also play an important role as advocates for better programming, alternative leisure activities, and promoting parental involvement.

Parental Health Needs.

Health supervision of children is a unique access point to provide guidance and improve the health status of the entire family. Studies have shown the health status of parents, for example, maternal depression, has significant influences on adequacy of preventive health care services for children. There is also evidence that significant health needs exist among women attending well child visits and that they are receptive to having pediatricians play a role in screening and referral for comprehensive health supervision. This role of pediatricians to influence the health of families is consistent with enhanced health supervision guidelines and a natural link to improve the health of children.

Literacy Promotion.

The positive effect of early educational interventions on the subsequent cognitive development of children demands that pediatricians play a role in promoting this aspect of family life and early childhood development. Reach Out and Read, a program in which books are distributed at well child visits, increases family literacy orientation, particularly for families living in poverty. Pediatricians may easily incorporate educational messages about the importance of reading to infants and children in health supervision visits. Alternatively, they may promote reading within their offices or at a local or community level by establishing and supporting literacy promotion programs.

Reducing Cardiovascular Disease.

Pediatricians should refer children who are at risk for cardiovascular disease for appropriate management. Long-term studies of pediatric patients demonstrate that elevated lipids and blood pressure track into adulthood. Obesity is an additional risk. All children should be monitored for obesity and, starting at age 2 yr, educated about appropriate intake of dietary fat (no more than 30% of calories), saturated fat (less than 10% of total calories), and dietary cholesterol (less than 300?mg/day). (See Chapters 43 and 75.3 .) Blood pressure measurements should be done at every well child visit starting at age 3 yr. Children with a positive family history for premature cardiovascular disease in a parent (younger than age 55 yr) or grandparent or a parent with high blood cholesterol should be screened with a total blood cholesterol, according to published guidelines (Chapter 75.3). In addition, pediatricians should encourage children to participate in active physical exercise to minimize the cardiovascular risks associated with a sedentary lifestyle.

Overview.

Preventive pediatrics requires commitment of pediatricians to constant improvement of the health of children and families. The topics touched upon here are merely a few of the issues that impact children's health and should be included in health supervision visits. The more pediatricians know about their patients and families, their cultural background, and the communities in which they live, the better able they will be to provide quality primary care, including prevention, to children and

families.

Chapter 6 - The Well Child

Paul L. McCarthy

The most powerful diagnostic technology available to pediatricians is the clinical evaluation: the process of observing the child, taking a history, and performing the physical examination. For pediatricians to maximize the benefit of the clinical evaluation, some of the complexities of this process must be appreciated (also see Chapter 5).

UNIQUE CHARACTER OF THE PEDIATRIC CLINICAL EVALUATION

This evaluation involves the physician, the parents, and the child. Historical information is often taken from the parents, and it is not until children reach later developmental stages that they can more actively contribute information about symptoms. These considerations change the manner in which pediatricians gather data about symptoms. Rather than asking, for example, if the child has abdominal pain, physicians ask questions that focus on the manner in which abdominal pain would present to an observer. Thus, questions about loss of appetite, sudden episodes of crying and drawing the legs up in a fetal position, or the child's crying when the parent has placed pressure on the abdomen are appropriate. A 24-mo-old child with a sore throat often does not complain of this but rather is observed by the parents to have more difficulty handling oral secretions, to refuse solids, and to have a foul breath odor. Questions are tailored to elicit this information.

As children become older, they may begin to add historical information that expresses symptoms in unique ways. The information provided by a child at times suggests the diagnosis precisely, but at other times a child's information may reflect a less developed sense of cause-and-effect relationships and may be at variance with the data provided by the parents. Thus, a 4-yr-old child with a urinary tract infection may be observed by the parent to be holding his or her abdomen and to have a subtle change in the frequency of urination. The child, on the other hand, may perceive that his or her abdominal complaints are related to a specific food that was ingested just before the onset of symptoms. In this instance, the pediatrician may conclude that the parents' history suggests the correct diagnosis (a urinary tract infection) by eliciting further information about, for example, discomfort when urinating.

PARENTS AND CHILD AS PARTICIPANTS IN THE CLINICAL EVALUATION

It is often left to the judgment of parents whether clinical symptoms should be brought to the attention of a physician. Moreover, children's interpretation of symptoms is intimately related to their developmental stage; this also influences the manner in which they transmit clinical information to a physician. Both parents and children must believe that the pediatrician is interested in their concerns and that interactions with the pediatrician will provide them support. This process occurs at both well and sick child visits. At well child visits, the parent or child might describe a specific behavior or symptom. The pediatrician demonstrates concern by listening attentively and by asking follow-up questions demonstrating that the behavior or symptom has been understood. These follow-up questions provide an opportunity for the parent or child to explore his or her own interpretation of these behaviors or symptoms, to understand their emotional response, and to learn from the interpretation provided by the physician. For example, parents reporting that their 9-mo-old child cries when being put to bed and has difficulty falling asleep offers an opportunity for the pediatrician to explore their interpretations of this behavior, to discuss their response to it, and to discuss individual variations in sleeping behavior. Based on this discussion and a more precise appreciation of the meaning of that behavior, strategies to facilitate sleeping can be suggested (Chapters 5 and 20.5).

The same interaction and education process occurs during sick child visits (see Chapter 49). Upper respiratory symptoms may concern parents. In response, the pediatrician may discuss the predominance of nasal breathing in younger children, the related symptoms of nasal stuffiness, and the absence of other evidence of serious pulmonary involvement, such as tachypnea. This enhances parents' abilities to interpret respiratory symptoms during subsequent upper respiratory infections. Similarly, the pediatrician can explain cause-and-effect relationships between infection and symptoms to an older child. Such encounters enhance the confidence of parents and children in their role as participants in the clinical evaluation. Studies have demonstrated the ability of parents to evaluate clinical data reliably and the ability of children, when given developmentally appropriate information, to improve their understanding of clinical causality.

DEVELOPMENTAL DIMENSIONS

The data generated from observation, history, and physical examination are greatly influenced by a child's developmental stage. A portion of the observational assessment of a child focuses on signs related to specific organ systems that are intimately related to age. A child of 1 mo has a more rapid respiratory rate (30 breaths/min) than a 3-yr-old child. An infant's respiratory rate is more sensitive to other influences, such as gastric pressure on the diaphragm caused by the recent ingestion of a meal, than is that of an older child. Other aspects of observational assessment focus on indicators of a child's overall state of well-being or functional status, such as how the child responds visually to the environment. These visual responses undergo developmental change as does the manner in which stimuli should be presented to elicit a child's optimal visual response. A 1-mo-old infant, for example, is more nearsighted and tends to focus on objects held within 1–2?ft of the face; objects presented in the peripheral fields of vision may be ignored. A young infant's ability to maintain attention on a visual stimulus is less developed than that of

an older child. Thus, pediatricians

must be aware of the developmental dimensions of observing children in order to gather and interpret clinical information accurately.

The data generated during the physical examination are also closely linked to a child's stage of development. Specific findings may be normal in one age group and abnormal in another. For example, a 1-mo-old child normally has a rooting reflex, which facilitates suckling. However, a rooting reflex found in a 2-yr-old child indicates central nervous system abnormalities. The manner in which physical examination findings are elicited also varies from one developmental stage to another. An 8-mo-old child, for example, is beginning to develop a sense of individuality and is aware of strangers and frightened by separation. Therefore, to elicit accurate physical examination data, especially during auscultation of the chest and heart, the examiner should allow the child to remain close to the parent and should approach as unobtrusively as possible. Factors that lessen the strangeness of a situation, such as the warmth of the room, the stethoscope, and the examiner's voice, also help facilitate data gathering. Older children are usually more comfortable with strangers and in separating from the parents; hence, after initial assurances, the physical examination may be done on the examination table.

GUIDELINES FOR EVALUATION

During the clinical encounter, it is often difficult to separate each component of the evaluation. As physicians are taking a history from a parent, they are observing the child and the interaction of the child with the parent; as physicians perform a physical examination, they are evaluating the child's global responses to the specific maneuver being performed. Nevertheless, certain guidelines can be followed during each part of the evaluation.

Observation is best done with a younger child in a comfortable position, usually on the parent's lap. Parental anxiety is easily transmitted to the child; thus, the parent and child must be placed at ease with a greeting and reassuring words. The tone of the examiner's voice is important and should convey a willingness to listen and a sensitivity to concerns being expressed. The manner in which an examiner is oriented to the parent and child is also important: If an examiner sits in one corner of a desk and focuses primarily on the patient's chart, a sense of unwillingness to communicate is conveyed. Sitting close to the parents and child and facing them directly are more effective. An examiner should observe the manner in which the parent and child are interacting: How are the parents responding to the child's needs, and, in turn, how is the child responding to the parents? Pediatricians can modulate the stimuli in this situation to gather important information by observation. The child may initially be clinging to the parent, so the pediatrician should interact with the child, offer the child an object, or attempt some separation of the child and parent to observe the child's response.

A history is best taken with a child in a comfortable position. If the child is quiet and comfortable, the parent can focus better on specific questions. Physicians vary in their amount of note taking during the history. Some prefer to write the history directly to progress notes; others note only key words and, at the end of the examination, transfer the information to the medical record. Whichever technique is used, it is critical that physicians remain responsive to the information being presented. If highly sensitive information is being conveyed and the parent or child is responding emotionally, physicians must convey empathic understanding. This is impossible, however, if note taking continues without interruption. Additional note taking during this critical moment can interfere with important observations about the parent and child and their interaction.

The precision and clarity with which parents and children describe symptoms vary. Ongoing interaction with a family over time enables pediatricians to learn how clinical information is perceived and transmitted within each family. If, for example, parents perceive their child as vulnerable, minor symptoms may be overemphasized; pediatricians can adjust the assessments accordingly.

The portions of the physical examination that require optimal cooperation are completed first: the blood pressure measurement, pulmonary and cardiac examinations, and evaluations of the eyes and central nervous system. A younger child may be held by the parent or seated on the parent's lap for these parts of the examination. An older child can be seated on the examination table. The pattern and rate of respirations are evaluated initially. Is there tachypnea? Is there increased work of breathing as manifested by subcostal, intercostal, or supraclavicular retractions? Is there an expiratory grunt indicating that the child is expiring against a closed glottis to keep the small airways open longer? What are the colors of the skin, nails, and mucous membranes? After these assessments have been made, the physician may proceed to palpation, percussion (if indicated), and auscultation. It is not uncommon for a younger child to cry as the stethoscope is placed on the chest, but this can usually be overcome by patience and by increasing the child's comfort, such as offering an infant a bottle. The same sequence may be followed for the cardiac examination. The ophthalmologic examination requires that the child be quietly wakeful; ophthalmoscopy can be done with the child in the parent's lap or as the child is being carried over the parent's shoulder. The other parent can sometimes provide visual stimuli; the retina can be seen more easily as the child focuses on such stimuli. Many portions of the neurologic examination, such as eliciting reflexes, also require cooperation and a state of quiet wakefulness. In an older child, this can be accomplished with the child on the examination table, but it is usually more helpful for a younger child to remain on the parent's lap.

After these portions of the examination, the examiner proceeds to the parts of the examination that are usually more bothersome to a child. Abdominal examination requires that a child be on the examination table. It is helpful to have the parent hold a younger patient's hand and speak reassuringly. Thus, the child does not tense the abdominal musculature unnecessarily as might occur during crying. After the abdominal examination, the pulses may be palpated, the genitalia examined, and the hips and extremities evaluated for clinical abnormalities. It is at this time that the examiner proceeds to the most intrusive portions of the examination, evaluation of the ear canals and tympanic membranes and examination of the oropharynx. During the ear examination, the parent may hold the child's head to minimize movement against the otoscope (Chapters 626 and 630). The examiner should recognize that the ear canals are highly sensitive, and the speculum should be introduced gently. The examiner's free hand can be used to put gentle traction on the pinna to

straighten the canal. A portion of the hand holding the otoscope, usually the 5th finger, should rest against the head so that the otoscope moves with the head. At times, depending on the amount of cooperation, the ears may be examined with the child in the parent's lap and the head resting against the parent's shoulder. The oropharyngeal examination is performed last, and the tongue blade is introduced gently.

The sequence of performing those portions of the physical examination that require inspection, palpation, percussion, and auscultation (pulmonary, cardiac, and abdominal) varies according to organ system. The most bothersome maneuvers are performed last. For example, during the cardiac examination, inspection can be followed by palpation and percussion and then by auscultation. For the abdominal examination, inspection should be followed by auscultation before percussion and palpation are completed.

With appropriate sensitivity to the child and the parent, an appreciation of the child's developmental stage, and concern for minimizing the discomfort of an examination, pediatricians can almost always obtain accurate clinical information and not cause undue upset to a child.

WELL CHILD EVALUATION

The broad principles of clinical data gathering that have been outlined apply to the well child examination. The recommended schedule of well child visits is outlined in Table 5–1 . For children with chronic or intercurrent problems, this sequence may vary (Chapter 37). Certain considerations should be addressed at each visit.

Open-Ended Questions.

Physicians should ask general questions that allow a parent or child to voice concerns that might not be raised if questions were too specific (also see Chapter 17). Open-ended questions such as “How are you?” or “How is the baby?” transmit an interest in the general well-being of the child and family. When such open-ended questions are asked, it is important that physicians explore the leads provided by the parents or child; ending the interaction prematurely, without appropriate follow-up questions, is frustrating to the parents and child and sends a mixed message about the physician's interest and concern.

Development.

Each well child visit should assess a child's developmental achievements; instruments such as the Denver Developmental Screening Test are helpful, with previous scores serving as reference points for evaluating changes (Chapter 16). As a child matures beyond 5 and 6 yr of age, questions that focus on school performance and talented accomplishments can be substituted for the Denver test. Reviewing developmental milestones with parents provides them with a sense of satisfaction in their child's progress and reinforces the efforts they are making to nurture and teach their children. Reviewing an older child's accomplishments is an important demonstration of support for these activities.

Feeding and Diet.

Many changes occur in the dietary intake of children and youth, and these should be reviewed with the parents and children (also see Chapter 41). The transitions from breast milk or infant formula to infant cereals, strained then junior foods, milk, and table foods, and the use of vitamins and fluoride are issues of daily concern for parents. In older children, the intake of excessive salt, carbohydrates, or cholesterol can adversely affect health. The rationale underlying the introduction of certain foods and dietary changes should be discussed with parents and children, so that they can make healthy choices.

Accident Prevention.

At each well child care visit, accident prevention should be reviewed (Chapters 5 and 50). Potential hazards around the home are emphasized, as are the importance of car safety measures and proper infant sleep position (on the back). Syrup of ipecac and the telephone number of the local poison control center should be given to the parents at the infant's 6 mo visit. The developmental aspect of accident prevention should be emphasized.

Growth.

At each well child visit, the height, weight, and head circumference are measured. These are plotted on standard graphs, such as those provided by the National Center for Health Statistics (see Chapter 15). It is important to review growth parameters with parents and children, because these are objective indicators of a child's progress. If abnormalities in the rate of growth are noted, the clinical evaluation can focus on possible causes. When interpreting these data, the pediatrician must focus on what is normal for this child, given the family background.

Family and Social Relations.

To grow and develop normally, children rely on the support and nurturance provided by their family and the social environment. Disturbances in these supports can lead to nonoptimal growth, altered development, and adverse behavioral changes. Pediatricians should assess these supports by observation and questions. Observations should include the hygiene of the child and the child's general level of interest and response to people. How do the parents respond to the child's needs? What is the tone of parents' voices as they discuss the child? In what terms do the parents describe the child? If the child begins crying or is disruptive, how do the parents respond? Do the parents face the young child or do they show lack of interest or concern? Does the child appear depressed or inappropriately anxious? Specific questions from the pediatrician may elucidate other stresses or strengths in the environment. Does the home environment, such as through inclusion of toys and books, nurture the child's developmental potential? Is there an extended network of friends and family that provides support to the children and parents? Is the family under significant stress, such as occurs during illness, moving, or loss of a job? A pediatrician's ability to gather information about these issues and to address them is

important in assessing health or dysfunction of a child and family.

A particular challenge is represented by the special needs of children who live in impoverished environments (Chapter 39). Empathizing with the difficulties of raising children in these circumstances, recognizing the obstacles that such children often face in realizing their potential, and assisting parents and children in overcoming some of these adversities are major responsibilities of pediatric care.

Anticipatory Guidance.

Based on a developmental orientation, physicians should be aware of issues that may present problems or questions for parents or children between the current and next visits. For example, the rate of growth of a 24-mo-old child lessens compared with that of previous months, and a diminished appetite results. Rather than have the parents be unnecessarily concerned about this, it is prudent to preview the child's rate of growth in the next 6 mo and to discuss its impact on food intake. The developmental achievements that the parents might expect in the next several months and the type of activities that facilitate these developments should also be discussed. For example, a 12-mo-old child's ability to grasp and bring objects to the mouth makes finger foods an option for a child at this age. In addition, this ability points out the need to remove small objects (e.g., peanuts) from the environment to minimize choking and aspiration hazards. The anticipatory guidance that is provided should also review issues in daily caretaking, such as hygiene and sleep patterns. See Chapter 5 .

Other Concerns.

At the initial well child visit, data about the family medical history and the prenatal and perinatal history should be entered into the medical record. At each well child visit, physicians should record and provide a record of immunizations to parents, notes should be made about any intercurrent illness and laboratory screening tests, and a review of systems should be carried out. After the physical examination is completed, the child's health status should be summarized for the parents. The parents should be complimented on their strengths as caregivers and children complimented about their achievements and progress. It is also important to recognize problems and to express willingness to work on these together with the family. The pediatrician's availability, if problems arise before the next visit, should be stressed to reassure the parents and child about the pediatrician's involvement in ongoing care. Lastly, parents and children should again be given an opportunity to ask questions or raise concerns about any aspect of the well child visit.

Part 2 - Growth and Development

Robert D. Needlman

Chapter 7 - Overview and Assessment of Variability

Pediatricians need to understand growth and development in order to monitor children's progress, to identify delays or abnormalities in development, and to counsel parents and prescribe treatment. In addition to clinical experience and personal knowledge, effective practice requires familiarity with major theoretical perspectives and evidence-based strategies for optimizing growth and development. In order to target factors that increase or decrease risk, pediatricians need to understand how biologic and social forces interact within the parent-child relationship, within the family, and between the family and the larger society. By monitoring children and families, pediatricians can observe the interrelationships between physical growth and cognitive, motor, and emotional development. At the same time, observation is enhanced by familiarity with developmental theory.

BIOPSYCHOSOCIAL MODELS OF DEVELOPMENT

Development is not determined solely by genetics (nature), nor is the child only a product of the environment (nurture). Rather, biopsychosocial models recognize the importance of both intrinsic and extrinsic forces. Height, for example, is a function of a child's genetic endowment (biologic), personal habits of eating (psychologic), and access to nutritious food (social).

Research demonstrating the profound impact of early experience on the development of the brain has illuminated the interaction of nature and nurture. The brain comprises 100 billion neurons at birth, with each neuron developing on average 15,000 synapses by 3 yr of age. The number of synapses stays roughly constant through the first decade of life, although the number of neurons declines. As some synapses develop, others disappear. Frequently used pathways are preserved, whereas less-used ones are deleted. Thus, experience (nurture) has a direct effect on the physical properties of the brain (nature). Children with different talents and temperaments (nature) also elicit different stimuli from their environment (nurture), and even when environmental inputs are identical, may interpret those inputs differently.

Early experience is particularly important because learning proceeds more efficiently along established synaptic pathways. Traumatic experiences may create enduring alterations in the neurotransmitter and endocrine systems that mediate the stress response, possibly increasing the risk of mental illness later in life. But experiences, positive or negative, rarely *determine* outcomes. Rather, they shift the probabilities one way or another, by influencing the child's ability to respond adaptively to future stimuli. The idea that a child's developmental course is essentially set by 3, 6, or 16 yr of age is not supported by the evidence.

Although biologic, psychologic, and social factors combine to shape development, it is helpful to consider each class of influence separately.

Biologic Influences.

Biologic influences on development include genetics, in utero exposure to teratogens, postpartum illnesses, exposure to hazardous substances, and maturation. Adoption and twin studies consistently show that heredity accounts for approximately half of the variance in IQ, and in other personality traits such as sociability and desire for novelty. The specific genes underlying these traits have begun to be identified. The effects on development of prenatal exposure to teratogens such as mercury and alcohol, and of postpartum insults such as meningitis and traumatic brain injury, have been extensively studied. Any chronic illness can affect growth and development, either directly or through changes in parenting or peer experiences.

Physical and neurologic maturation propels children forward and sets lower limits for the emergence of most abilities. The age at which children walk independently is similar around the world, despite great variability in child-rearing practices. Other attainments (e.g., the use of complex sentences) are less tightly bound to a maturational schedule. Maturational changes also generate behavioral challenges at predictable times. For example, decrements in growth rate and sleep requirements around 2 yr of age often generate concerns about poor appetite and refusal to nap. While it is possible to accelerate many developmental milestones—for example, toilet training a 12 mo old or teaching a 3 yr old to read—the long-term benefits of such precocious accomplishments are questionable.

In addition to physical changes in size, body proportions, and strength, maturation brings about hormonal changes. Sexual differentiation, both somatic and neurologic, begins in utero. Behavioral effects of testosterone may be evident even in young children and continue to be salient throughout life. However, correlations between testosterone and such traits as aggression or novelty-seeking have not been consistently demonstrated.

A biologic influence of particular clinical importance is temperament. Temperament refers to a child's characteristic style of responding. The classic theory proposes nine parameters of temperament (Table 7–1). Although temperament is intrinsic to a child and relatively resistant to modification by parenting practices, most temperamental characteristics show only modest stability over time. Active, intense

2-yr-olds, for example, do not necessarily grow into active, intense 22-yr-olds.

The concept of temperament is clinically useful in two ways. First, it can help parents understand and accept the characteristics of their children without feeling responsible for having caused them. Second, behavioral and emotional problems often develop when the temperamental characteristics of children and parents conflict. Active children may be especially problematic for low-key parents; children who are "slow to warm up" may feel especially pressured if their parents are very outgoing; parents who lead highly structured lives may have a hard time meeting the needs of children whose biologic urges occur on an especially irregular schedule. "Goodness of fit" between the child and parents is a powerful predictor of outcome.

Psychologic Influences: Attachment and Contingency.

The influence of the child-rearing environment dominates most current models of development. Erik Erikson identified the 1st yr of life as a time when "basic trust" was established through the mother's

TABLE 7-1 -- **Temperamental Characteristics: Descriptions and Examples**

Characteristic	Description	Example*
Activity level	Amount of gross motor movement	"She ran before she walked." "He would rather sit still than run around."
Rhythmicity	Regularity of biologic cycles	"He is never hungry at the same time each day." "You could set a watch by her nap."
Approach and withdrawal	Typical response to a new stimulus	"She rejects every new food at first." "He loves new people."
Adaptability	How long it takes to adapt to novel stimulus	"Changes upset him." "She adjusts to new people quickly."
Threshold of responsiveness	How intense do stimuli need to be to evoke a response (e.g., feel, sound, light)	"Underwear and socks bother him; he does not like anything touching his skin." "She will eat anything, wear anything, do anything."
Intensity of reaction	How much energy a child expends in emotions and actions	"She shouts when she is happy and wails when she is sad." "He never cries much."
Quality of mood	Usual disposition (e.g., pleasant, glum)	"He does not laugh much." "It seems like she is always happy."
Distractibility	How easily diverted from ongoing activity	"Her mind is always wandering." "He will listen through a whole story."
Attention span and persistence	How long a child pays attention and sticks with difficult tasks	"He goes from toy to toy every minute." "She will keep at a puzzle until she has mastered it."

* *Typical statements of parents, reflecting the range for each characteristic from very little to very much.*

consistent responsiveness to her child's needs. In the 1950s, studies of infants in hospitals and foundling homes documented the devastating effects of maternal deprivation and pointed to the importance of attachment. Attachment refers to a biologically determined tendency of a young child to seek proximity with the parent during times of stress and also to the relationship that allows securely attached children to use their parents to re-establish a sense of well-being after a stressful experience. Insecure attachment may be predictive of later behavioral and learning problems.

At all stages of development children progress optimally when they have adult caregivers who pay attention to their verbal and nonverbal cues and respond accordingly. In early infancy, such contingent responsiveness to signs of overarousal or underarousal helps maintain infants in a state of quiet alertness and fosters autonomic self-regulation. Contingent responses to nonverbal gestures create the groundwork for the shared attention and reciprocity critical for later language and social development. Children learn best when new challenges are just slightly harder than what they have already mastered, a degree of difficulty dubbed the "zone of proximal development."

Social Factors: Family Systems and the Ecologic Model.

Contemporary models of child development recognize the critical importance of influences outside of the mother-child dyad. Increasingly, fathers are recognized as playing critical roles, both in their direct relationships with their children, and in supporting mothers. As traditional "nuclear" families become less dominant, the influence of other family members—grandparents, foster and adoptive parents, and nonrelated caregivers—becomes increasingly clear.

Families function as systems, with internal and external boundaries, subsystems, roles, and rules for interaction. In families with rigidly defined parental subsystems, children may be denied any decision-making at all, exacerbating rebelliousness. In families with relatively porous parent-child boundaries, children may be "parentified," required to take on responsibilities beyond their years or recruited to play a spousal role.

Individuals within systems adopt implicit roles. One child is the "troublemaker," another is the "negotiator," another is "quiet." Birth order may have profound effects on personality development, through its influence on family roles and patterns of interaction. Families are also dynamic: Changes in one person's behavior affect every other member of the system; roles shift until a new equilibrium is found. The birth of a new child, attainment of developmental milestones such as independent walking, the onset of nighttime fears, and the death of a grandparent are all changes that require renegotiation of roles within the family and have the potential for healthy

adaptation or dysfunction.

The family system, in turn, functions within the larger systems of extended family, subculture, culture, and society (see Chapters 3 and 4). The ecologic model depicts these relationships as concentric circles, with the parent-child dyad at the center and the larger society at the periphery. Changes at any level are reflected in the levels above and below. The shift from an industrial economy to one based on service and information is an obvious example of societal change with profound effects on families and children.

Unifying Concepts: The Transactional Model, Risk, and Resilience.

The transactional model proposes that a child's status at any point in time is a function of the interaction between biologic and social influences. The influences are bidirectional: Biologic factors such as temperament and health status both affect the child-rearing environment and are affected by it. For example, a premature infant may cry little and sleep for long periods; the infant's depressed parent may welcome this “good” behavior, setting up a cycle that leads to poor nutrition and inadequate growth. The child's failure to thrive may reinforce the parent's sense of failure as a parent. At a later stage, impulsivity and inattention associated with early prolonged undernutrition may lead to a referral for aggressive behavior. The “cause” of the aggression in this case is not the prematurity, the undernutrition, or the maternal depression but the interaction of all these factors.

Conversely, children with biologic risk factors may nevertheless do well developmentally if the child-rearing environment is supportive. For example, premature infants with electroencephalographic evidence of neurologic immaturity may be at increased risk of cognitive delay. However, this risk may only be realized when the quality of parent-child interaction is poor. When parent-child interactions are optimal, even moderate prematurity carries a low risk of developmental disability.

Children growing up in poverty are in double developmental jeopardy, because of increased exposure to biologic risk factors such as environmental lead and undernutrition, and decreased access to corrective educational and therapeutic experiences (see Chapters 34 and 39). When early intervention programs provide timely, intensive, comprehensive, and prolonged services (i.e., a level of support that economically advantaged families often take for granted) at-risk children show marked and sustained upswings in their developmental trajectory. Early identification of children at developmental risk, along with early intervention to support parenting, is critically important.

A rough estimate of developmental risk can begin with a tally of risk factors, such as low income, limited parental education, and exposure to community violence. One classic study, for example, documented a nearly linear relationship between developmental outcome at age 13 yr and the number of social and family risk factors at age 4 yr (Fig. 7–1). But protective factors also have to be considered. These factors, like risk factors, may be either biologic (temperamental persistence, athletic talent) or social. In a famous study of children growing up in Hawaii, for

Figure 7-1 Relationship between mean IQ scores at 13 yr (both raw and adjusted for covariation of mother's IQ), as related to the number of risk factors. (From Sameroff AJ, Seifer R, Baldwin A, Baldwin C: Stability of intelligence from preschool to adolescence: The influence of social and family risk factors. *Child Dev* 1993;64:80.)

example, the personal histories of children who overcame poverty generally included at least one trusted adult—a parent, grandparent, or teacher—with whom the child had a special, supportive close relationship.

Developmental Domains and Theories of Emotion and Cognition.

Another approach to child development tracks development within particular domains such as gross motor, fine motor, social, emotional, language, and cognition. Within each of these categories are developmental lines or sequences of changes leading up to particular attainments. Developmental lines in the gross-motor domain, leading from rolling to creeping to independent walking, are obvious. Others, such as the line leading to the development of conscience, are more subtle.

The concept of a developmental line implies that a child passes though successive stages. The psychoanalytic theories of Sigmund Freud and Erik Erikson and the cognitive theory of Jean Piaget share the idea of stages as qualitatively different epochs in the development of emotion and cognition (Table 7–2). In contrast, the behavioral theory of Skinner relies less on qualitative change and more on the gradual modification of behavior and accumulation of competence.

PSYCHOANALYTIC THEORIES.

At the core of *freudian theory* is the idea of body-centered (or broadly “sexual”) drives. The focus of the drives shifts with maturation from oral satisfactions (i.e., sucking in the 1st yr of life); to anal sensations (i.e., holding on and letting go during the toddler years); oedipal drives (possessiveness toward a parent in the preschool years), and genital drives (in puberty and beyond) (see Table 7–2). At each stage, the child's drive can potentially conflict with the rules of society. For example, the infant may want to suck longer than his mother wants to nurse; or the toddler may decide he *likes* making a mess. The emotional health of the child and adult depends on adequate resolution of these conflicts. Freud saw middle childhood as a period of *latency*, when the sexual drive is redirected (sublimated) to the achievement of social or external goals.

Freudian ideas have come under broad attack. For example, few believe that the manner of toilet training permanently shapes personality, and middle childhood is no longer seen as conflict-free. Moreover, the effectiveness of psychoanalytic therapy has been difficult to demonstrate empirically. Nonetheless, the freudian legacy includes concepts that are central to an understanding of emotional development: the importance of a child's inner life and sexuality, the normative existence of emotional conflict during childhood, and the possibility that emotional disturbance

can have early roots.

Erikson's chief contribution was to recast Freud's stages in terms of the emerging personality (see Table 7–2). For example, the child's sense of *basic trust* develops through the successful negotiation of infantile needs, corresponding to Freud's oral period. As children progress through these psychosocial stages, different issues become salient. Thus, it is predictable that a preschool-age child will be preoccupied with establishing his or her sense of autonomy, whereas a late adolescent may be more focused on establishing meaningful relationships and an occupational identity. Erikson recognized that these stages arise in the context of Western European societal expectations; in other cultures, the salient issues may be quite different.

Erikson's work calls attention to the intrapersonal challenges facing children at different ages in a way that facilitates professional intervention. For example, knowing that the salient issue for school-aged children is industry vs inferiority, pediatricians know to inquire about a child's experiences of mastery and failure and (if necessary) suggest ways to ensure adequate successes.

Piaget is synonymous with the study of cognitive development. A central tenet of piagetian thought is that cognition changes in quality, not just quantity (see Table 7–2). During the sensorimotor stage, an infant's thinking is tied to immediate sensations and a child's ability to manipulate objects. For example, the concept of "in" is embodied in a child's act of putting a block into a cup. With the arrival of language, the nature of thinking changes

TABLE 7-2 -- **Classic Stage Theories**

Theory	Infancy (0–1 yr)	Toddlerhood (2–3 yr)	Preschool (3–6 yr)	School Age (6–12 yr)	Adolescence (12–20 yr)
Freud: psychosexual	Oral	Anal	Oedipal	Latency	Adolescence
Erikson: psychosocial	Basic trust	Autonomy vs shame and doubt	Initiative vs guilt	Industry vs inferiority	Identity vs identity diffusion
Piaget: cognitive	Sensorimotor (stages I–IV)	Sensorimotor (stages V, VI)	Preoperational	Concrete operations	Formal operations

dramatically; symbols increasingly take the place of objects and actions. Cognitive stages correspond to the major periods of childhood: preoperational (preschool); concrete operations (school age); and formal operations (adolescence). Piaget described how children actively construct knowledge for themselves through the linked processes of assimilation (seeking experience) and accommodation (adapting their implicit ideas about the world to take new information into account). In this way, children act as "little scientists," creating ever more adaptive and complex theories. The stages of cognitive reorganization can be mapped by observing children and by asking open-ended questions that make the implicit theories explicit.

Piaget's basic concepts have held up well. Challenges have included questions about the timing of various stages, the role of formal teaching, and the extent to which context may affect conclusions about cognitive stage. For example, children's understanding of cause and effect may be considerably more advanced in the context of sibling relationships than in the context of inanimate objects (e.g., various machines); in many children, logical thinking appears well before puberty, the age postulated by Piaget. Of undeniable importance are Piaget's focus on cognition as a subject of empirical study, the universality of the progression of cognitive stages (even if details of timing are controversial), and the image of a child as actively and creatively interpreting the world.

Piaget's work is of special importance to pediatricians for three reasons: (1) It helps make sense of many puzzling behaviors of infancy, such as the common exacerbation of sleep problems at 9 and 18 mo of age; (2) Piagetian observations often lend themselves to quick replication in the office, with little special equipment; and (3) Open-ended questioning, based on Piaget's work, can provide insights into children's understanding of illness and hospitalization.

BEHAVIORAL THEORY.

This theoretical perspective distinguishes itself by its lack of concern with a child's inner experience. Its sole focus is on observable behaviors and measurable factors that either increase or decrease the frequency with which these behaviors occur. No stages are implied: Children, adults, and indeed animals all respond the same. In its simplest form, the behaviorist orientation asserts that behaviors that are positively reinforced occur more frequently; behaviors that are negatively reinforced or ignored occur less frequently.

The strengths of this position are its simplicity, wide applicability, and conduciveness to scientific verification. A behavioral approach lends itself to readily taught interventions for various common problems such as temper tantrums and nocturnal enuresis. In cognitively limited children and children with autism spectrum disorders, behavioral interventions utilizing applied behavior analysis (ABA) approaches have demonstrated their ability to teach new, complex behaviors. However, in cases in which misbehavior is symptomatic of an underlying emotional, perceptual, or family problem, an exclusive reliance on behavior therapy risks leaving the cause untreated.

Statistics Used in Describing Growth and Development (see also Chapters 15 and 16).

In everyday use, the term *normal* is synonymous with *healthy*. In a statistical sense, *normal* means that a set of values generates a normal (bell-shaped, or gaussian) distribution. This is the case with anthropometric quantities such as height and weight, and with many developmental milestones such as the age of independent standing. For a normally distributed measurement, a histogram with the quantity (e.g., height, or age) on the *x*-axis and the frequency (the number of children of that height, or the number who stand on their own at that age) on the *y*-axis generates a bell-shaped curve. In an ideal bell-shaped curve, the peak corresponds to the arithmetic mean of the sample, and to the median and the mode as well. The median is the value above and below which 50% of the observations lie; the mode is the

value having the highest number of observations. Distributions are termed *skewed* if the mean, median, and mode are not the same number.

The extent to which observed values cluster near the mean determines the width of the bell and can be described mathematically by the standard deviation (SD). In the ideal normal curve, a range of values extending from 1 SD below the mean to 1 SD above the mean includes approximately 68% of the values, and each “tail” above and below that range contains 16% of the values. A range encompassing ±2 SD includes 95% of the values (with the upper and lower tails each comprising approximately 2.5% of the values), and ±3 SD encompasses 99.7% of the values (Table 7–3 , Fig. 7–2).

TABLE 7-3 -- **Relationship Between SD and Normal Range for Normally Distributed Quantities**

Observations Included in Normal Range		Probability of a “Normal” Measurement Deviating from Mean by This Amount	
SD	***%***	***SD***	***%***
±1	68.3	=1	16.0
±2	95.4	=2	2.3
±3	99.7	=3	0.13

SD = standard deviation.

Figure 7-2 Relationship between percentile lines on the growth curve and frequency distributions of height at different ages.

Figure 7-3 Method of presenting percentiles for developmental milestones.

For any single measurement, its distance away from the mean can be expressed in terms of the number of SDs (also called a *z score*); one can then consult a table of the normal distribution to find out what percentage of measurements fall within that distance from the mean. Software to convert anthropometric data into z-scores for epidemiologic purposes is readily available. A measurement that falls “outside the normal range”—arbitrarily defined as 2, or sometimes 3 SD on either side of the mean—is atypical, but not necessarily indicative of illness. However, the further a measurement (say, height, weight, or IQ) falls from the mean, the greater the probability that it represents not simply the normal variation, but rather a different, potentially pathologic, condition.

Another way of relating an individual to a group uses percentiles. The percentile is the percentage of individuals in the group who have achieved a certain measured quantity (e.g., a height of 95?cm) or developmental milestone. For anthropometric data, the percentile cutoffs can be calculated from the mean and SD. The 5th, 10th, and 25th percentiles correspond to -1.65 SD, -1.3 SD, and -0.7 SD, respectively. Figure 7–2 shows conceptually how frequency distributions of a particular parameter (height) at different ages relate to the percentile lines on the growth curve. For developmental milestones, the percentiles are often displayed in boxes, derived from graphs plotting age (*x*-axis) against the percentage of subjects achieving the particular milestone (*y*-axis), as shown in Figure 7–3 .

Chapter 8 - Fetal Growth and Development

The most dramatic events in growth and development occur before birth. This chapter traces the transformation of fertilized egg into embryo and fetus, the elaboration of the nervous system, and the emergence of behavior in utero. Also important are the psychologic changes occurring in the parents during the period of gestation. With processes so complex, much can go wrong. The uterus is permeable to adverse social and environmental influences such as maternal undernutrition; alcohol, cigarette, and drug use (both legal and illicit); and perhaps psychologic trauma. The complex interplay between these forces and the somatic and neurologic transformations occurring in the fetus influences infants' behavior at birth and may affect parent-child interactions throughout infancy.

Somatic Development

EMBRYONIC PERIOD.

Milestones of prenatal development are presented in Table 8–1 . By 6 days postconceptual age, as implantation begins, the embryo consists of a spherical mass of cells with a central cavity (the blastocyst). By 2 wk, implantation is complete and the uteroplacental circulation has begun; the embryo has two distinct layers, endoderm and ectoderm, and the amnion has begun to form. By 3 wk, the third primary germ layer (mesoderm) has appeared, along with primitive neural tube and blood vessels. Paired heart tubes have begun to pump.

During wk 4–8, lateral folding of the embryologic plate, followed by growth at the cranial and caudal ends and the budding of arms and legs, produces a human-like shape. Precursors of skeletal muscle and vertebrae (somites) appear, along with the branchial arches that will form the mandible, maxilla, palate, external ear, and other head and neck structures. Lens placodes appear, marking the site of future eyes; the brain grows rapidly. By the end of wk 8, as the embryonic period closes, the rudiments of all major organ systems have developed; the average embryo weighs 9?g and has a crown-rump length of 5?cm.

FETAL PERIOD.

From the 9th wk on (the fetal period), somatic changes consist of increases in cell number and size and structural remodeling of several organ systems. Changes in body proportion are depicted in Figure 8–1 . By 10 wk, the face is recognizably human. The midgut returns from the umbilical cord into the abdomen, rotating counterclockwise to bring the stomach, small intestine, and large intestine into their normal positions. By 12 wk, the gender of the external genitals becomes clearly distinguishable. Lung development proceeds with the budding of bronchi, bronchioles, and successively smaller divisions. By 20–24 wk, primitive alveoli have formed and surfactant production has begun; before that time, the absence of alveoli renders the lungs useless as organs of gas exchange.

During the 3rd trimester, weight triples and length doubles as body stores of protein, fat, iron, and calcium increase (see Chapter 85). Low birthweight may be due to prematurity,

TABLE 8-1 -- **Milestones of Prenatal Development**

Week	Developmental Events
1	Fertilization and implantation; beginning of embryonic period
2	Endoderm and ectoderm appear (bilaminar embryo)
3	First missed menstrual period; mesoderm appears (trilaminar embryo); somites begin to form
4	Neural folds fuse; folding of embryo into human-like shape; arm and leg buds appear; crown-rump length 4–5?mm
5	Lens placodes, primitive mouth, digital rays on hands
6	Primitive nose, philtrum, primary palate; crown-rump length 21–23?mm
7	Eyelids begin
8	Ovaries and testes distinguishable
9	Fetal period begins; crown-rump length 5?cm; weight 9?g
10	External genitals distinguishable
20	Usual lower limit of viability; weight 460?g; length 19?cm
25	Third trimester begins; weight 900?g; length 25?cm
28	Eyes open; fetus turns head down; weight 1,300?g
38	Term

Figure 8-1 Changes in body proportions from the 2nd fetal mo to adulthood. (From Robbins WJ, Brody S, Hogan AG, et al: *Growth*. New Haven, Yale University Press, 1928.)

intrauterine growth retardation (small for dates), or both (see Chapter 86).

Neurologic Development.

During the 3rd wk, a neural plate appears on the ectodermal surface of the trilaminar embryo. Infolding produces a neural tube that will become the central nervous system (CNS) and a neural crest that will become the peripheral nervous system. Neuroectodermal cells differentiate into neurons, astrocytes, oligodendrocytes, and ependymal cells, whereas microglial cells are derived from mesoderm. By the 5th wk, the three main subdivisions of forebrain, midbrain, and hindbrain are evident. The dorsal and ventral horns of the spinal cord have begun to form, along with the peripheral motor and sensory nerves. Myelinization begins at midgestation and continues throughout the 1st 2 yr of life.

By the end of the embryonic period (wk 8), the gross structure of the nervous system has been established. On a cellular level, the growth of axons and dendrites and the elaboration of synaptic connections continue at a rapid pace, making the CNS vulnerable to teratogenic or hypoxic influences throughout gestation. Rates of increase in DNA (a marker of cell number), overall brain weight, and cholesterol (a marker of myelinization) are shown in Figure 8–2 . The prenatal and postnatal peaks of DNA probably represent rapid growth of neurons and glia, respectively.

Figure 8-2 Velocity curves of the various components of human brain growth. Solid line with two peaks = DNA; dashed line = brain weight; single peak solid line = cholesterol. (From Brasel JA, Gruen RK: In Falkner F, Tanner JM [editors]: *Human Growth: A Comprehensive Treatise*. New York, Plenum Press, 1986, pp 78–95.)

Behavioral Development.

Muscle contractions first appear around 8 wk, soon followed by lateral flexion movements. By 13–14 wk, breathing and swallowing motions appear and tactile stimulation elicits graceful movements. The grasp reflex appears at 17 wk and is well developed by 27 wk. Eye opening occurs around 26 wk. By midgestation, the full range of neonatal movements can be observed.

During the 3rd trimester, fetuses respond to external stimuli with heart rate elevation and body movements. As with infants in the postnatal period, reactivity to auditory (vibroacoustic) and visual (bright light) stimuli vary depending on their behavioral state, which can be characterized as quiet sleep, active sleep, and awake. Individual differences in the level of fetal activity are commonly noted by mothers and have been observed ultrasonographically. Fetal behavior is affected by maternal medications and diet, increasing, for example, after ingestion of caffeine, and may be entrained to the mother's diurnal rhythms.

Fetal movement increases in response to a sudden auditory tone, but decreases after several repetitions (habituation). If the tone changes in pitch, the movement increases again, evidence that the fetus distinguishes between a familiar, repeated tone and a novel one. The ability to habituate to repeated stimuli, a form of learning, is diminished in neurologically impaired or physically stressed fetuses. Similar responses to visual and tactile stimuli have been observed.

Psychologic Changes in Parents.

The psychologic changes during pregnancy fall roughly into three stages. Stage 1 begins when a woman first learns that she is pregnant. Ambivalent feelings are the norm, whether or not the pregnancy was planned. Elation at the thought of producing a baby and the wish to be the perfect parent compete with fears of inadequacy and of the lifestyle changes that mothering will impose. Old conflicts may resurface as a woman psychologically identifies with her own mother and with herself as a child. The father-to-be faces similar mixed feelings, and problems in the parental relationship may intensify.

Stage 2 begins with awareness of fetal movements, or quickening, at approximately 20 wk or earlier with ultrasonic visualization. This palpable evidence that a fetus exists as a separate being often heightens a woman's feelings, both positive and negative. Parents worry about the fetus's healthy development and mentally rehearse what they will do if the child is malformed. Reassurances based on ultrasound examinations or amniocentesis may not completely allay these fears. During stage 3, toward the end of pregnancy, a woman becomes aware of patterns of fetal activity and reactivity and begins to ascribe to her fetus an individual personality and an ability to survive independently. Appreciation of the psychologic vulnerability of the expectant mother and father and of the powerful contribution of fetal behavior facilitates supportive clinical intervention.

Threats to Fetal Development.

Mortality and morbidity are highest during the prenatal period (see Chapter 82). Some 30% of pregnancies end in spontaneous abortion, most often during the 1st trimester as a result of chromosomal or other abnormalities. Major congenital malformations requiring neonatal surgical intervention occur in approximately 2% of live births. Teratogens associated with gross physical and mental abnormalities include various infectious agents (toxoplasmosis, rubella, syphilis), chemical agents (mercury, thalidomide, antiepileptic medications, ethanol), high temperature, and radiation (see Chapters 85 and 700).

For any potential teratogen, the extent and nature of its effects are determined by characteristics of the host as well as the dose and timing of the exposure. Inherited differences in the metabolism of ethanol may predispose certain individuals or groups to fetal alcohol syndrome, for example. Organ systems are most vulnerable during periods of maximum growth and differentiation, generally during the first trimester (organogenesis). Figure 8–3 depicts sensitive periods during gestation for various organ systems.

Figure 8-3 Schematic illustration of the sensitive or critical periods in prenatal development. Dark boxes denote highly sensitive periods; light boxes indicate states that are less sensitive to teratogens. (From Moore KL: *Before We Are Born: Basic Embryology and Birth Defects*, 2nd ed. Philadelphia, WB Saunders, 1977.)

Teratogenic effects may include not only gross physical malformation but also decreased growth and cognitive or behavioral deficits that only become apparent later in life. Prenatal exposure to cigarette smoke is associated with lower birthweight, shorter length, and smaller head circumference, as well as decreased IQ and increased rates of learning disabilities. The effects of prenatal exposure to cocaine remain controversial, and may be less dramatic than popularly believed. In addition to direct neurotoxic effects and effects mediated by reduced placental blood flow, associated risk factors include other prenatal exposures (e.g., alcohol and cigarettes used in large amounts by many cocaine-addicted women) as well as “toxic” postnatal environments frequently characterized by instability, multiple caregivers, and abuse and neglect (see Chapter 95). The wide range of outcomes observed reflects the complex interactions among biologic and social risk and protective factors. High levels of psychologic stress during pregnancy may also adversely affect fetal development.

Chapter 9 - The Newborn

Infants thrive physically and psychologically only in the context of their social relationships. Therefore, any description of the newborn's developmental status has to include consideration of the parents' role as social partners as well.

DETERMINANTS OF PARENTING (see Chapter 83)

Parenting a newborn infant requires dedication because a newborn's needs are urgent, continuous, and often unclear. To know what to do, parents must attend to an infant's signals and respond empathically. Many factors influence parents' ability to assume this role.

Prenatal Factors.

Pregnancy is a period of psychological preparation for the profound demands of parenting. Most women experience ambivalence, particularly (but not exclusively) if their pregnancy was unplanned. If financial worries, physical illness, prior miscarriages or stillbirths, or other crises interfere with their working through the ambivalence, the neonate may arrive as an unwelcome guest. For adolescent mothers, the demand that they relinquish their own developmental agenda (e.g., the need for an active social life) may be especially burdensome.

The early experience of being mothered may establish unconsciously held expectations about nurturing relationships that permit mothers to “tune in” to their infants. Research has linked the quality of these expectations (or working models) with the quality of later infant-parent interactions. Mothers whose early childhoods were marked by traumatic separations, abuse, or neglect may find it especially difficult to provide consistent, responsive care. Instead, they may re-enact their childhood experiences with their own infants as if unable to conceive of the mother-child relationship in any other way. Maternal depression, during pregnancy and in the postpartum period, undermines the mother-child relationship, and may threaten the infant's cognitive and emotional development.

Social support during pregnancy—particularly support from the father—is also important. Conversely, conflict with or abandonment by the father during pregnancy may diminish the mother's ability to become absorbed with her infant. Anticipation of an early return to work makes it hard for many women to allow themselves to fall in love with their babies, because they are already anticipating having to separate from them. After 4–6 mo, both mothers and babies are more likely to handle the separation smoothly.

Peripartum and Postpartum Influences.

Numerous randomized, prospective trials show that the continuous presence during labor of a woman trained to offer friendly support and encouragement (a doula) results in shorter labor, fewer obstetric complications (including cesarean section), and reduced postpartum hospital stays. Skin-to-skin contact between mothers and infants immediately after birth may correlate with an increased rate and longer duration of breast-feeding. Most new parents value even a brief period of uninterrupted time in which to get to know their new infants, and increased mother-infant contact over the first days of life may improve long-term mother-child interactions. Nonetheless, early separation, although predictably very stressful, does not inevitably impair a mother's ability to bond with her infant. Early discharge home from the maternity ward may undermine bonding, particularly when a new mother is required to resume full responsibility for a busy household.

THE INFANT'S CONTRIBUTION

Interactional Abilities.

Soon after birth, neonates are alert and ready to interact and nurse, if given the opportunity. This first alert-awake period may be affected by maternal analgesics and anesthetics or fetal hypoxia. Nearsighted neonates have a fixed focal length of 8–12 in, approximately the distance from the breast to the mother's face, as well as an inborn visual preference for faces. Hearing is well developed, and infants preferentially turn toward a female voice. These innate abilities and predilections increase the likelihood that when a mother gazes at her newborn, the baby will gaze back. The initial period of social interaction, usually lasting about 40?min, is followed by a period of somnolence. After that, briefer periods of alertness or excitation alternate with sleep. If a mother misses her baby's first alert-awake period (because she has been anesthetized), she may not experience as long a period of social interaction for several days.

Modulation of Arousal.

Adaptation to extrauterine life requires rapid and profound physiologic changes, including aeration of the lungs, rerouting of the circulation, and activation of the intestinal tract. The necessary behavioral changes are no less profound. To obtain nourishment, to avoid hypo-and hyperthermia, and to ensure safety, neonates must react appropriately to an expanded range of sensory stimuli. Infants must become aroused in response to stimulation but not so overaroused that behavior becomes utterly disorganized. Underaroused infants are not able to feed and interact; overaroused infants show signs of autonomic instability, including flushing or mottling, perioral pallor, hiccuping, vomiting, uncontrolled limb movements, or inconsolable crying.

Behavioral States.

The organization of infant behavior into discrete behavioral states may reflect an

infant's inborn ability to regulate arousal. Six states have been described: quiet sleep, active sleep, drowsy, alert, fussy, and crying. In the alert state, infants visually fixate on objects or faces and follow them horizontally and (within a month) vertically; they also reliably turn toward a novel sound, as if searching for its source. When overstimulated,

---

they may calm themselves by looking away, yawning, or sucking on their lips or hands, thereby increasing parasympathetic activity and reducing sympathetic nervous activity. The behavioral state determines an infant's muscle tone, spontaneous movement, electroencephalogram pattern, and response to stimuli. In active sleep, for example, an infant may show progressively less reaction to a repeated heel prick (habituation), whereas in the drowsy state the same stimulus may push a child into fussing or crying.

Mutual Regulation.

Parents actively participate in an infant's state regulation, alternately stimulating or soothing with the goal of prolonging the social interaction. In turn, the parents are regulated by the infant's signals, for example, responding to cries of hunger with a letdown of milk (or with a bottle). Such interactions constitute a system directed toward furthering the infant's physiologic homeostasis and physical growth. At the same time, they form the basis for the emerging psychologic relationship between parent and child. Infants come to associate the presence of the parent with the pleasurable reduction of tension (as in feeding) and show this preference by calming more quickly for the mother than for a stranger. This response, in turn, strengthens a mother's sense of efficacy and connection with her baby.

CLINICAL IMPLICATIONS: THE PHYSICIAN'S ROLE

Pediatric interventions to support healthy newborn development include (1) promoting optimal medical practices before, during, and after delivery; (2) assessing parent-infant interactions; and (3) teaching parents about their newborn's individual competencies and vulnerabilities.

Optimal Practices.

A prenatal pediatric visit allows pediatricians to assess potential threats to bonding (e.g., a tense spousal relationship) and sources of social support and to try to allay unrealistic fears. Supportive hospital policies include the use of birthing rooms rather than operating suite/delivery rooms; encouragement for the father or a trusted relative or friend to remain with the mother during labor or the provision of a professional support person or doula; the practice of giving the newborn infant to the mother immediately after drying and brief assessment; placement of the newborn in the mother's room rather than in a central nursery; and avoiding in-hospital distribution of infant formula. Such policies have been shown to significantly increase breast-feeding rates. After discharge (often within 24?hr of delivery), home visits by nurses and lactation counselors can reduce early feeding problems and identify early-emerging medical conditions. Such family-focused policies may be particularly important for ill infants. Infants requiring transport to another hospital should be brought to see the mother first if at all possible. On discharge home, fathers can shield mothers from unnecessary visits and calls and take over household duties, allowing mothers and infants to get to know each other without distractions.

Assessing Parent-Infant Interactions.

During a feeding or when infants are alert and face to face with parents, it is normal for them to appear absorbed in one another. Infants who become overstimulated by the mother's voice or activity may turn away or close their eyes, leading to a premature termination of the encounter. Alternatively, the infant may be ready to interact, whereas the mother may appear preoccupied. Asking a new mother about her own emotional state, and inquiring specifically about a history of depression, facilitates referral for therapy, which may provide long-term benefits to the child.

Teaching About Individual Competencies.

The Newborn Behavior Assessment Scale (NBAS) provides a formal measure of an infant's neurodevelopmental competencies, including state control, autonomic reactivity, reflexes, habituation, and orientation toward auditory and visual stimuli. This examination can also be used to demonstrate to parents an infant's capabilities and vulnerabilities. Parents might learn that they need to undress their infant to increase the level of arousal or to swaddle the infant to reduce overstimulation by containing random arm movements. The NBAS can be used to support the development of positive early parent-infant relationships. Demonstration of the NBAS in the 1st wk of life has been shown to correlate with improvements in the caretaking environment months later.

Chapter 10 - The First Year

During the first year of life, physical growth, maturation, acquisition of competence, and psychologic reorganization occur in discontinuous bursts. These changes qualitatively change a child's behavior and social relationships. Children acquire new competences in the gross motor, fine motor, cognitive, and emotional domains. The concept of developmental lines highlights how more complex skills build on simpler ones; but it is also important to realize how development in each domain affects functioning in all of the others. Physical growth parameters and normal ranges for attainable weight, length, and head circumference can be estimated as noted in Tables 10–1 and 10–2 . Table 10–3 presents an overview of key milestones by domain, whereas Table 10–4 presents similar information arranged cross-sectionally.

AGE 0–2 MONTHS

The biologic and psychologic challenges facing neonates and their parents were described in Chapter 9 . These consist of establishing effective feeding routines and a predictable sleep-wake cycle. The social interactions that occur as parents and infants accomplish these tasks lay the foundation for cognitive and emotional development.

Physical Development.

A newborn's weight may decrease 10% below birthweight in the 1st wk as a result of excretion of excess

TABLE 10-1 -- **Formulas for Approximate Average Height and Weight of Normal Infants and Children**

Weight	Kilograms	(Pounds)
At birth	3.25	(7)
3–12 mo		(age [mo] + 11)
1–6 yr	age (yr) × 2 + 8	(age [yr] × 5 + 17)
7–12 yr		age (yr) × 7 + 5

Height	Centimeters	(Inches)
At birth	50	(20)
At 1 yr	75	(30)
2–12 yr	age (yr) × 6 + 77	(age [yr] × 21/2 + 30)

Data used in creating the 2000 Centers for Disease Control (CDC) growth charts, as described in English units appear in parentheses, below the corresponding metric units. Data apply to the age the listed age and subsequent month (i.e., "1 mo" represents the average for 1 mo, 0 days through days). Data for additional age points and 3rd and 97th percentiles are available at www.cdc.gov/nc technical reports.

TABLE 10-3 -- **Developmental Milestones in the First 2 Yr of Life**

Milestone	Average Age of Attainment (mo)	Developmental Implications
Gross Motor		
Head steady in sitting	2.0	Allows more visual interaction
Pull to sit, no head lag	3.0	Muscle tone
Hands together in midline	3.0	Self-discovery
Asymmetric tonic neck reflex gone	4.0	Child can inspect hands in midline
Sits without support	6.0	Increasing exploration
Rolls back to stomach	6.5	Truncal flexion, risk of falls
Walks alone	12.0	Exploration, control of proximity to parents
Runs	16.0	Supervision more difficult
Fine Motor		
Grasps rattle	3.5	Object use
Reaches for objects	4.0	Visuomotor coordination
Palmar grasp gone	4.0	Voluntary release
Transfers object hand to hand	5.5	Comparison of objects
Thumb-finger grasp	8.0	Able to explore small objects
Turns pages of book	12.0	Increasing autonomy during book time
Scribbles	13.0	Visuomotor coordination
Builds tower of two cubes	15.0	Uses objects in combination
Builds tower of six cubes	22.0	Requires visual, gross, and fine motor coordination
Communication and Language		
Smiles in response to face, voice	1.5	Child more active social participant
Monosyllabic babble	6.0	Experimentation with sound, tactile sense
Inhibits to "no"	7.0	Response to tone (nonverbal)
Follows one-step command with gesture	7.0	Nonverbal communication
Follows one-step command without gesture	10.0	Verbal receptive language _ (e.g., "Give it to me")
Speaks first real word	12.0	Beginning of labeling
Speaks 4–6 words	15.0	Acquisition of object and personal names
Speaks 10–15 words	18.0	Acquisition of object and personal names

Speaks two-word sentences (e.g., “Mommy shoe”)	19.0	Beginning grammaticization, corresponds with 50+ word vocabulary
Cognitive		
Stares momentarily at spot where object disappeared	2.0	Lack of object permanence (out of sight, out of mind)_ (e.g., yarn ball dropped)
Stares at own hand	4.0	Self-discovery, cause and effect
Bangs two cubes	8.0	Active comparison of objects
Uncovers toy (after seeing it hidden)	8.0	Object permanence
Egocentric pretend play (e.g., pretends to drink from cup)	12.0	Beginning symbolic thought
Uses stick to reach toy	17.0	Able to link actions to solve problems
Pretend play with doll (gives doll bottle)	17.0	Symbolic thought

extravascular fluid and possibly poor intake. Intake improves as colostrum is replaced by higher-fat milk, as infants learn to latch on and suck more efficiently, and as mothers become more comfortable with feeding techniques. Infants should regain or exceed birthweight by 2 wk of age and should grow at approximately 30?g (1?oz)/day during the 1st mo (Table 10–5). Limb movements consist largely of uncontrolled writhing, with apparently purposeless hand opening and closing. Smiling occurs involuntarily. In contrast, eye gaze, head turning, and sucking are under better control and thus can be used to demonstrate infant perception and cognition. For example, an infant's preferential turning toward the mother's voice is evidence of recognition memory.

Six behavioral states have been described (see Chapter 9). Initially, sleep and wakefulness are evenly distributed throughout the 24?hr (Fig. 10–1). Neurologic maturation accounts for the consolidation of sleep periods into longer and longer blocks. Learning has a role as well. Infants whose parents are consistently more interactive and stimulating during the day learn to concentrate their sleeping during the night. By 2 mo of age, most infants are waking briefly two or three times to feed; some sleep 6?hr or more at a stretch. Crying occurs in response to stimuli that may be obvious (a soiled diaper) but are often obscure. Crying normally peaks at about 6 wk of age, when healthy infants cry up to 3?hr/day, then decreases to 1?hr or less by 3 mo.

Cognitive Development.

Caretaking activities provide visual, tactile, olfactory, and auditory stimuli; all of these support the development of cognition. Studies of habituation and gaze preference provide insights into how infants interpret these stimuli. Infants habituate to the familiar, attending less and less to repeated stimuli and increasing their attention when the stimulus changes. Experiments using habituation and renewed attention as outcomes show that infants can differentiate among similar patterns, colors, and consonants. They can recognize facial expressions (smiles) as similar, even when they appear on different faces. They also can match abstract properties of stimuli, such as contour, intensity, or temporal pattern across sensory modalities. For example, 3-wk-old infants can tell whether a spoken voice corresponds to the movements of the lips on a videotape. Blindfolded and given a bumpy pacifier to suck, they subsequently gaze longer at the bumpy pacifier than at a smooth one when both are presented visually.

Such studies suggest that infants are able to perceive objects and events as coherent, even while noting aspects that are discrepant. These abilities allow infants to sort stimuli into meaningful sets: a set of stimuli that correspond to sucking as well as others that correspond to sucking a bottle, sucking a pacifier, and sucking a finger. Infants appear to seek stimuli actively as though satisfying an innate need to make sense of the world.

Emotional Development.

Basic trust, the first of Erikson's psychosocial stages, develops as infants learn that their urgent needs are met regularly. The consistent availability of a trusted adult creates the conditions for a secure attachment. Infants who are consistently picked up and held in response to distress cry less at 1 yr and show less aggressive behavior at 2 yr.

TABLE 10-4 -- **Emerging Patterns of Behavior During the 1st Yr of Life**

	Neonatal Period (1st 4 Wk)
Prone:	Lies in flexed attitude; turns head from side to side; head sags on ventral suspension
Supine:	Generally flexed and a little stiff
Visual:	May fixate face or light in line of vision; “doll's-eye&” movement of eyes on turning of the body
Reflex:	Moro response active; stepping and placing reflexes; grasp reflex active
Social:	Visual preference for human face
	At 4 Wk
Prone:	Legs more extended; holds chin up; turns head; head lifted momentarily to plane of body on ventral suspension
Supine:	Tonic neck posture predominates; supple and relaxed; head lags on pull to sitting position
Visual:	Watches person; follows moving object

Social:	Body movements in cadence with voice of other in social contact; beginning to smile
	At 8 Wk
Prone:	Raises head slightly farther; head sustained in plane of body on ventral suspension
Supine:	Tonic neck posture predominates; head lags on pull to sitting position
Visual:	Follows moving object 180 degrees
Social:	Smiles on social contact; listens to voice and coos
	At 12 Wk
Prone:	Lifts head and chest, arms extended; head above plane of body on ventral suspension
Supine:	Tonic neck posture predominates; reaches toward and misses objects; waves at toy
Sitting:	Head lag partially compensated on pull to sitting position; early head control with bobbing motion; back rounded
Reflex:	Typical Moro response has not persisted; makes defensive movements or selective withdrawal reactions
Social:	Sustained social contact; listens to music; says "aah, ngah"
	At 16 Wk
Prone:	Lifts head and chest, head in approximately vertical axis; legs extended
Supine:	Symmetric posture predominates, hands in midline; reaches and grasps objects and brings them to mouth
Sitting:	No head lag on pull to sitting position; head steady, tipped forward; enjoys sitting with full truncal support
Standing:	When held erect, pushes with feet
Adaptive:	Sees pellet, but makes no move to it
Social:	Laughs out loud; may show displeasure if social contact is broken; excited at sight of food
	At 28 Wk
Prone:	Rolls over; pivots; crawls or creep-crawls (Knobloch)
Supine:	Lifts head; rolls over; squirming movements
Sitting:	Sits briefly, with support of pelvis; leans forward on hands; back rounded
Standing:	May support most of weight; bounces actively
Adaptive:	Reaches out for and grasps large object; transfers objects from hand to hand; grasp uses radial palm; rakes at pellet
Language:	Polysyllabic vowel sounds formed
Social:	Prefers mother; babbles; enjoys mirror; responds to changes in emotional content of social contact
	At 40 Wk
Sitting:	Sits up alone and indefinitely without support, back straight
Standing:	Pulls to standing position; "cruises" or walks holding on to furniture
Motor:	Creeps or crawls
Adaptive:	Grasps objects with thumb and forefinger; pokes at things with forefinger; picks up pellet with assisted pincer movement; uncovers hidden toy; attempts to retrieve dropped object; releases object grasped by other person
Language:	Repetitive consonant sounds (mama, dada)
Social:	Responds to sound of name; plays peek-a-boo or pat-a-cake; waves bye-bye
	At 52 Wk (1 Yr)
Motor:	Walks with one hand held (48 wk); rises independently, takes several steps (Knobloch)
Adaptive:	Picks up pellet with unassisted pincer movement of forefinger and thumb; releases object to other person on request or gesture
Language:	A few words besides "mama," "dada"
Social:	Plays simple ball game; makes postural adjustment to dressing

Data are derived from those of Gesell (as revised by Knobloch), Shirley, Provence, Wolf, Bailey, and others.

The emotional significance of any experience depends on an individual child's temperament as well as the parent's responses. Consider the impact of different feeding schedules. Hunger generates increasing tension; as the urgency peaks, the infant cries, the parent arrives with a bottle or breast, and the tension dissipates. Infants fed "on demand" consistently experience this link between their distress, the arrival of the parent, and the relief from hunger. Most infants fed on a fixed schedule quickly adapt their hunger cycle to the schedule. Those who cannot because they are temperamentally prone to irregular biologic rhythms experience periods of unrelieved hunger as well as unwanted feedings when they already feel full. Similarly, infants fed at the parents' convenience, with neither attention to the infant's hunger cues nor a fixed schedule, may not consistently experience feeding as the pleasurable reduction of tension. These infants often show increased irritability and physiologic instability (spitting, diarrhea, poor weight gain) as well as later behavioral problems.

Implications for Parents and Pediatricians.

Success or failure in establishing feeding and sleep cycles determines parents' feelings

TABLE 10-5 -- Growth and Caloric Requirements

Age	Approximate Daily Weight Gain (g)	Approximate Monthly Weight Gain	Growth in Length (cm/mo)	Growth in Head Circumference (cm/mo)	Recommended Daily Allowance (kcal/kg/day)
0–3 mo	30	2?lb	3.5	2.00	115
3–6 mo	20	1 1/4?lb	2.0	1.00	110
6–9 mo	15	1?lb	1.5	0.50	100
9–12 mo	12	13?oz	1.2	0.50	100
1–3 yr	8	8?oz	1.0	0.25	100
4–6 yr	6	6?oz	3?cm/yr	1?cm/yr	90–100

Adapted from National Research Council, Food and Nutrition Board: Recommended Daily Allowances. Washington, DC, National Academy of Sciences, 1989; Frank D, Silva M, Needlman R: Failure to thrive: Myth and method. Contemp Pediatr 1993; 10:114.

of efficacy. When things go well, the parents' anxiety and ambivalence, as well as the exhaustion of the early weeks, relent. With physical recovery from delivery and endocrinologic normalization, the mild postpartum depression that affects some 50% of mothers (“baby blues”) passes. If sad, overwhelmed, anxious feelings persist, the possibility of moderate to severe postpartum depression needs to be considered. Major depression that arises during pregnancy or in the postpartum period threatens the mother-child relationship and is a risk factor for later cognitive and behavioral problems.

AGE 2–6 MONTHS

At about 2 mo, the emergence of voluntary (social) smiles and increasing eye contact mark a change in the parent-child relationship, heightening the parents' sense of being loved back.

Figure 10-1 Typical sleep requirements in children. (From Ferber R: *Solve Your Child's Sleep Problems*. New York, Simon & Schuster, 1985.)

During the next months, an infant's range of motor and social control and cognitive engagement increases dramatically. Mutual regulation takes the form of complex social interchanges.

Physical Development.

Between 3 and 4 mo, the rate of growth slows to approximately 20?g/day (see Table 10–5 and Figs. 11–1 and 11–2). Early reflexes that limited voluntary movement recede. Disappearance of the asymmetric tonic neck reflex means that infants can begin to examine objects in the midline and manipulate them with both hands. Waning of the early grasp reflex allows them both to hold objects and voluntarily to let them go. A novel object may elicit purposeful though inefficient reaching. The quality of spontaneous movements also changes, from larger writhing to smaller, circular movements that have been described as “fidgety.” Abnormal or absent fidgety movements may constitute a risk factor for later neurologic abnormalities.

Increasing control of truncal flexion makes intentional rolling possible. Infants who routinely sleep on their backs (to prevent sudden infant death syndrome) may learn to roll somewhat later. Once infants can hold their head steady while sitting, they can gaze across at things rather than merely up at them, and can begin taking food from a spoon. At the same time, maturation of the visual system allows greater depth of field.

Total sleep requirements are approximately 14–16?hr/24?hr, with about 9–10?hr concentrated at night; about 70% of infants sleep for a 6-to 8-hr stretch by age 6 mo (see Fig. 10–1). By 4–6 mo, the sleep electroencephalogram shows a mature pattern, with demarcation of rapid eye movement (REM) and four stages of non-REM sleep. The sleep cycle remains shorter than in adults (50–60?min, versus approximately 90). As a result, infants arouse to light sleep or wake frequently during the night, setting the stage for behavioral sleep problems.

Cognitive Development.

The overall effect of these developments is a qualitative change in an infant. Four-month-old infants are described as “hatching” socially, becoming interested in a wider world. During feeding, infants no longer focus exclusively on the mother but become distracted. In the mother's arms, the infant may literally turn around, preferring to face outward.

Infants at this age also explore their own bodies, staring intently at their hands, vocalizing, blowing bubbles, and touching their ears, cheeks, and genitals. These explorations represent an early stage in the understanding of cause and effect as infants learn that voluntary muscle movements generate predictable tactile and visual sensations. They also have a role in the emergence of a sense of self. Infants come to associate certain sensations through frequent repetition. For example, the proprioceptive feeling of holding up the hand and wiggling the fingers always accompanies the sight of the fingers moving. Such “self” sensations are consistently linked and reproducible at will. In contrast, sensations that come to be classed as “nonself” occur with less regularity and in varying combinations. The sound, smell, and feel of mother sometimes appears promptly in response to crying but sometimes does not.

Emotional Development and Communication.

Outward-looking babies interact with increasing sophistication and range. The primary emotions of anger, joy, interest, fear, disgust, and surprise appear in appropriate contexts as distinct facial expressions. Face to face with a trusted adult, the infant and adult match affective expressions about 30% of the time; the intensity of their smiling, eye widening, and lip puckering rises and falls together. Every few seconds, as excitement builds, the infant turns away, settles, and then returns to the interaction. If the parent turns away, the infant leans forward, reaches, or in other ways tries to get the adult involved again; if that fails, the infant cries angrily.

Infants of depressed parents show a different pattern, spending less time in coordinated movement with their parents and making fewer efforts to re-engage. Rather than anger, they show sadness and a loss of energy when the parents continue to be unavailable. Such face-to-face behavior reveals the infant's ability to share emotional states, the first step in the development of communication; it also shows infants' (and parents') developing expectations about social relationships.

Implications for Parents and Pediatricians.

Motor and sensory maturation makes infants at 3–6 mo exciting and interactive, at once cuter and more appealing but also more separate than at a younger age. Some parents experience their 4-mo-old's outward turning as a rejection, secretly fearing that their infants no longer love them. For most parents, however, this is a happy period. Most parents excitedly report that they can hold “conversations” with their infants, taking turns vocalizing and listening. Pediatricians share in the enjoyment, as the baby flirts and coos. If this visit does not feel joyful and relaxed, causes such as social stress, family dysfunction, parental mental illness, or problems in the infant-parent relationship should be considered.

AGE 6–12 MONTHS

Months 6–12 bring increased mobility and exploration of the inanimate world, advances in cognitive understanding and communicative competence, and new tensions around the themes of attachment and separation. Infants develop will and intentions, characteristics that most parents welcome but still find challenging to manage.

Physical Development.

Growth slows more (see Table 10–5 and Figs. 11–1 and 11–2). The ability to sit unsupported (about 7 mo) and to pivot while sitting (around 9–10 mo) provides increasing opportunities to manipulate several objects at a time and to experiment with novel combinations of objects. These explorations are aided by the emergence of a pincer grasp (around 9 mo). Many infants begin crawling and pulling to stand around 8 mo and walk before their first birthday either independently or in a walker. Motor achievements correlate with increasing myelinization and cerebellar growth.

These ambulatory achievements expand infants' exploratory range and create new physical dangers as well as opportunities for learning. Tooth eruption occurs, usually starting with the mandibular central incisors (Table 10–6). Tooth development also reflects, in part, skeletal maturation and bone age (Table 10–7).

Cognitive Development.

At first, everything goes into the mouth; in time, novel objects are picked up, inspected, passed from hand to hand, banged, dropped, and then mouthed. Each action represents a nonverbal idea about what things are for (in piagetian terms, a schema). The complexity of an infant's play, how many different schemata are brought to bear, is a useful index of cognitive development at this age. The pleasure, persistence, and energy with which infants tackle these challenges suggest the existence of an intrinsic drive or mastery motivation. Mastery behavior occurs when infants feel secure; those with less secure attachments show limited experimentation and less competence.

A major milestone is the achievement (about 9 mo) of object constancy, the understanding that objects continue to exist even when not seen. At 4–7 mo, infants look down for a yarn ball that has been dropped but quickly give up if it is not seen. With object constancy, infants persist in searching, finding objects hidden under a cloth or behind the examiner's back.

Emotional Development.

The advent of object constancy corresponds with qualitative changes in social and communicative development. Infants look back and forth between an approaching stranger and a parent, as if to contrast known from unknown, and may cling or cry anxiously. Separations often become more difficult. Infants who have been sleeping through the night for months begin to awaken regularly and cry, as though remembering that parents are in the next room.

At the same time, a new demand for autonomy emerges. Infants no longer consent to be fed but turn away as the spoon approaches or insist on holding it themselves. Self-feeding with finger foods allows infants to exercise newly acquired fine

The norms present a composite of published data from the Fels Research Institute, Yellow Springs, OH (Pyle SI, Sontag L: Am J Roentgenol 49:102, 1943), and unpublished data from the Brush Foundation, Case Western Reserve University, Cleveland, OH, and the Harvard School of Public Health, Boston, MA. Compiled by Lieb, Buehl, and Pyle.		

* To nearest month.
† Except for the capitate and hamate bones, the variability of carpal centers is too great to make them very useful clinically.
‡ Standards for the foot are available, but normal variation is wide, including some familial variants, so that this area is of little clinical use.

motor skills (the pincer grasp); it may be the only way to get a child to eat. Tantrums make their first appearance as the drives for autonomy and mastery come in conflict with parental controls and with the infants' still-limited abilities.

Communication.

Infants at 7 mo are adept at nonverbal communication, expressing a range of emotions and responding to vocal tone and facial expressions. Around 9 mo, infants become aware that emotions can be shared between people; they show parents toys gleefully, as if to say, “When you see this thing, you'll be happy, too!” Between 8 and 10 mo, babbling takes on a new complexity, with many syllables (“ba-da-ma”) and inflections that mimic the native language. At the same time, infants lose the ability to distinguish between vocal sounds that are undifferentiated in their native language. The first true word—i.e., a sound used consistently to refer to a specific object or person—appears in concert with an infant's discovery of object constancy.

At this age, picture books provide an ideal context for verbal language acquisition. With a familiar book as a shared focus of attention, a parent and child engage in repeated cycles of pointing and labeling, with elaboration and feedback by the parent.

Implications for Parents and Pediatricians.

With the developmental reorganization around 9 mo, previously resolved issues of feeding and sleeping re-emerge. Pediatricians can prepare parents at the 6-mo visit so that these problems can be understood as the results of developmental progress and not regression. Parental ambivalence about separation can express itself in a delay in introducing finger foods or drinking from a cup (usually before the 1st birthday) or an intrusive, overly neat approach to meal times. Poor weight gain at this age often reflects a struggle between an infant and parent over control of the infant's eating. Discussions about an infant's drive for autonomy and need for limited choices may avert such problems.

Infants' wariness of strangers often makes the 9-mo examination difficult, particularly if the infant is temperamentally prone to react negatively to unfamiliar situations. Time spent talking with the mother and playing with the child will be rewarded by more cooperation. By using picture books as part of the routine health supervision visit, pediatricians can effectively promote reading aloud while addressing a variety of behavioral issues, including object exploration, autonomy, attention, language, and the continued importance of physical closeness and shared enjoyment.

Chapter 11 - The Second Year

At approximately 18 mo of age, the emergence of symbolic thought causes a reorganization of behavior with implications across many developmental domains.

AGE 12–18 MONTHS

Physical Development.

The growth rate slows further in the 2nd yr of life (see Table 10–5) and appetite declines. “Baby fat” is burned up by increased mobility; exaggerated lumbar lordosis makes the abdomen protrude. Brain growth continues, with myelinization throughout the 2nd yr (see Fig. 8–2).

Most children begin to walk independently near their first birthday; some do not walk until 15 mo. Highly active, fearless infants tend to walk earlier; less active, more timid infants and those who are preoccupied with exploring objects in detail walk later. Early walking is not associated with advanced development in other domains.

At first, infants toddle with a wide-based gait, knees bent, and arms flexed at the elbow; the entire torso rotates with each stride; the toes may point in or out, and the feet strike the floor flat. Subsequent refinements lead to greater steadiness and energy efficiency. After several months of practice, the center of gravity shifts back and the torso stays more stable, while knees extend and arms swing at the sides for balance. The toes are held in better alignment, and the child is able to stop, pivot, and stoop without toppling over.

Cognitive Development.

As toddlers master reaching, grasping, and releasing, and greater mobility gives them access to more and more objects, exploration increases. Toddlers combine objects in novel ways to create interesting effects, such as stacking blocks or putting things into a videocassette recorder slot. Playthings are also more likely to be used for their intended purposes (combs for hair, cups for drinking). Imitation of parents and older children is an important mode of learning. Make-believe play centers on the child's own body (pretending to drink from an empty cup) (Table 11–1 ; see also Table 10–3).

Emotional Development.

Infants developmentally approaching the milestone of their first steps may be irritable. Once they start walking, their predominant mood changes markedly. Toddlers are described as “intoxicated” with their new ability and with the power to control the distance between themselves and their parents. Exploring toddlers orbit around their parents, like comets around the sun, moving away, then returning for a reassuring touch before moving away again. In unfamiliar surroundings, with temperamentally timid children, such orbits might be small or nonexistent; in familiar ones, a bold child might orbit out of sight (see Table 11–1).

A child's ability to use the parent as a secure base for exploration depends on the attachment relationship. Attachment is typically assessed using the so-called “strange situation” procedure, in which the parents temporarily leave the child in an unfamiliar playroom. When their parents leave, most children stop playing, cry, and try to follow. The child's security of attachment is coded based on his or her response upon the parents' return. Securely attached children instantly go to their parents to be picked up, are comforted, and then are able to return to play. Children with ambivalent attachments go to their parents but then may resist being comforted and may hit at their parents in anger. Children categorized as avoidant may not protest when the parents leave and may turn away upon the parents' return. Insecure response patterns may represent strategies infants develop to cope with punitive or unresponsive parenting styles and may predict later cognitive and emotional problems. Controversy continues about how infant temperament and prior experience of separations might affect the interpretation of strange situation results.

Linguistic Development.

Receptive language precedes expressive. By the time infants speak their first words, around 12 mo, they already respond appropriately to several simple statements such as “no,” “bye-bye,” and “give me.” By 15 mo, the average child points to major body parts and uses four to six words spontaneously and correctly, including proper nouns. Toddlers also enjoy polysyllabic jargoning (see Tables 10–3 and 11–1) but do not seem upset that no one understands. Most communication of wants and ideas continues to be nonverbal.

Implications for Parents and Pediatricians.

Parents who cannot recall any other milestone tend to remember when their child began to walk, perhaps because of the symbolic significance of walking as an act of independence. A child's ability to wander out of sight also obviously increases the risks of injury and need for supervision. When walking is precluded by physical disability, parents and care providers should facilitate exploration and help the child attain greater control over separation and proximity through wheelchairs or other assistance.

Patterns of response similar to those rated in the strange situation procedure may be observable in the pediatric clinic. Many toddlers are comfortable exploring the examination room but cling to the parents under the stress of the examination. Infants who become more, not less, distressed in their parents' arms or who avoid their parents at times of stress may be insecurely attached. Young children who, when distressed, turn to strangers for comfort rather than to parents are particularly worrisome.

AGE 18–24 MONTHS

Physical Development.

Motor development is incremental at this age, with improvements in balance and agility and the emergence of running and stair climbing. Height and weight increase at a steady rate, although head growth slows slightly (Figs. 11–1 and 11–2 ; see also Table 10–5).

Cognitive Development.

At approximately 18 mo, several cognitive changes come together to mark the conclusion of the sensorimotor period. Object permanence is firmly established; toddlers anticipate where an object will end up, even though the object was not visible while it was being moved. Cause and effect are better understood, and toddlers demonstrate flexibility in problem solving, for example using a stick to obtain a toy out of reach or figuring out how to wind a mechanical toy. Symbolic transformations in play are no longer tied to the toddler's own body, so that a doll can be “fed” from an empty plate. Like the reorganization at 9 mo, the cognitive changes at 18 mo correlate with important changes in the emotional and linguistic domains (see Table 11–1).

Emotional Development.

In many children, the relative independence of the preceding period gives way to increased clinginess around 18 mo. This stage, described as *rapprochement*, may be a reaction to growing awareness of the possibility of separation. Many parents report that they now cannot go anywhere without having a small child attached to them. Separations at bedtime are often difficult, with frequent false starts and tantrums. Many children use a special blanket or stuffed toy as a transitional

TABLE 11-1 -- **Emerging Patterns of Behavior from 1 to 5 Yr of Age**[*]

	15 Mo
Motor:	Walks alone; crawls up stairs
Adaptive:	Makes tower of 3 cubes; makes a line with crayon; inserts pellet in bottle
Language:	Jargon; follows simple commands; may name a familiar object (ball)
Social:	Indicates some desires or needs by pointing; hugs parents
	18 Mo
Motor:	Runs stiffly; sits on small chair; walks up stairs with one hand held; explores drawers and wastebaskets
Adaptive:	Makes a tower of 4 cubes; imitates scribbling; imitates vertical stroke; dumps pellet from bottle
Language:	10 words (average); names pictures; identifies one or more parts of body
Social:	Feeds self; seeks help when in trouble; may complain when wet or soiled; kisses parent with pucker
	24 Mo
Motor:	Runs well, walks up and down stairs, one step at a time; opens doors; climbs on furniture; jumps
Adaptive:	Tower of 7 cubes (6 at 21 mo); circular scribbling; imitates horizontal stroke; folds paper once imitatively
Language:	Puts 3 words together (subject, verb, object)
Social:	Handles spoon well; often tells immediate experiences; helps to undress; listens to stories with pictures
	30 Mo
Motor:	Goes up stairs alternating feet
Adaptive:	Tower of 9 cubes; makes vertical and horizontal strokes but generally will not join them to make a cross; imitates circular stroke, forming closed figure
Language:	Refers to self by pronoun “I”; knows full name
Social:	Helps put things away; pretends in play
	36 Mo
Motor:	Rides tricycle; stands momentarily on one foot
Adaptive:	Tower of 10 cubes; imitates construction of “bridge” of 3 cubes; copies a circle; imitates a cross
Language:	Knows age and sex; counts 3 objects correctly; repeats 3 numbers or a sentence of 6 syllables
Social:	Plays simple games (in “parallel” with other children); helps in dressing (unbuttons clothing and puts on shoes); washes hands
	48 Mo
Motor:	Hops on one foot; throws ball overhand; uses scissors to cut out pictures; climbs well
Adaptive:	Copies bridge from model; imitates construction of “gate” of 5 cubes; copies cross and square; draws a man with 2 to 4 parts besides head; names longer of 2 lines
Language:	Counts 4 pennies accurately; tells a story
Social:	Plays with several children with beginning of social interaction and role-playing; goes to toilet alone
	60 Mo

Motor:	Skips
Adaptive:	Draws triangle from copy; names heavier of 2 weights
Language:	Names 4 colors; repeats sentence of 10 syllables; counts 10 pennies correctly
Social:	Dresses and undresses; asks questions about meaning of words; domestic role-playing

* *Data are derived from those of Gesell (as revised by Knobloch), Shirley, Provence, Wolf, Bailey, and others. After 5 yr the Stanford-Binet, Wechsler-Bellevue, and other scales offer the most precise estimates of developmental level. In order to have their greatest value, they should be administered only by an experienced and qualified person.*

object: something that functions as a symbol of the absent parent (in psychoanalytic terms, the object). The transitional object remains important until the transition to symbolic thought has been completed and the symbolic presence of the parent has been fully internalized. Individual differences in temperament, both in the child and the parents, play a critical role in determining the balance of conflict versus cooperation in the parent-child relationship.

Self-conscious awareness and internalized standards of evaluation first appear at this age. Toddlers looking in a mirror will, for the first time, reach for their own face rather than the mirror image if they notice a red dot on their nose or some other unusual appearance. They begin to recognize when toys are broken and may hand them to parents to fix. When tempted to touch a forbidden object, they may tell themselves “no, no,” evidence of internalization of standards of behavior. That they often go on to touch the object anyway demonstrates the relative weakness of internalized inhibitions at this stage (see Table 11–1).

Linguistic Development.

Perhaps the most dramatic developments in this period are linguistic. Labeling of objects coincides with the advent of symbolic thought. Children may point at things with their index finger rather than their whole hand as though calling attention to objects not for the purpose of having them but of finding out their names. When this protolinguistic naming is accompanied by the phrase “Whazzat?” the child's intentions are clear. After the realization that words can stand for things, a child's vocabulary balloons from 10–15 words at 18 mo to 100 or more at 2 yr. After acquiring a vocabulary of about 50 words, toddlers begin to combine them to make simple sentences, the beginning of grammar. At this stage, toddlers understand two-step commands, such as “Give me the ball and then get your shoes.” The emergence of verbal language marks the end of the sensorimotor period. As toddlers learn to use symbols to express ideas and solve problems, the need for cognition based on direct sensation and motor manipulation wanes (see Table 11–1).

Implications for Parents and Pediatricians.

With children's increasing mobility, physical limits on their explorations become less effective; words become increasingly important for behavior control as well as cognition. Children with delayed language

44

acquisition often have greater behavior problems. Language development is facilitated when parents and caregivers use clear, simple sentences, ask questions, and respond to children's incomplete sentences and gestural communication with the appropriate words. Regular periods of looking at picture books together continue to provide an ideal context for language development.

Pediatricians can help parents understand the resurgence of problems with separation and the appearance of a treasured blanket or teddy bear as a developmental phenomenon. Management of difficult behavior and assessment of children with delayed speech are discussed in Chapter 12 . Helping parents to understand and adapt to their children's different temperamental styles can constitute an important, and very appreciated, intervention.

Chapter 12 - Preschool Years

Between 2 and 5 yr of age, the core issues of attachment and separation are reshaped by the emergence of language and played out in the context of a widening social sphere. As toddlers, children learn to walk away and come back. As preschoolers, they explore emotional separation, alternating between stubborn opposition and cheerful compliance, between bold exploration and clinging dependence. Increasing time spent in classrooms and playgrounds challenges a child's ability to adapt to new rules and relationships. Preschool children know that they can do more than ever before, but they are also very aware of the constraints imposed on them by the adult world, and their own limited abilities.

PHYSICAL DEVELOPMENT (Tables 12–1 and 12–2)

By the end of the 2nd yr, somatic and brain growth slows, with corresponding decreases in nutritional requirements and in appetite (see Table 10–5). Between the ages of 2 and 5 yr, the average child gains approximately 2?kg in weight and 7?cm in height per year. The toddler's prominent abdomen flattens, and the body becomes leaner. Physical energy peaks, and the need for sleep declines to 11–13?hr/24?hr, usually including one nap (see Fig. 10–1). Visual acuity reaches 20/30 by age 3 yr and 20/20 by age 4. All 20 primary teeth have erupted by 3 yr of age (see Table 10–6).

Gross and fine motor milestones are presented in Table 10–4 . Most children walk with a mature gait and run steadily before the end of their 3rd yr. Beyond this basic level, there is wide variation in ability as the range of motor activities expands to include throwing, catching, and kicking balls; riding on bicycles; climbing on playground structures; dancing; and other complex pattern behaviors. Stylistic features of gross motor activity, such as tempo, intensity, and cautiousness, also vary significantly because of inborn predilections. Toe walking, if it persists, may be associated with developmental delays, particularly of speech and language.

The effects of such individual differences on cognitive and emotional development depend in part on the demands of the social environment. Energetic, coordinated children may thrive emotionally with parents or teachers who encourage physical activity; lower energy, more cerebral children may thrive with adults who value quiet play.

Handedness is usually established by the 3rd yr. Frustration may result from attempts to change children's hand preference. Variations in fine motor development reflect both individual proclivities and different opportunities for learning. Children who are seldom allowed to use crayons, for example, develop a mature pencil grasp

later.

Bowel and bladder control emerge during this period (average age 30 mo, with large individual and cultural variation). Daytime bladder control typically precedes bowel control, and girls precede boys. Bed-wetting is normal up to age 4 yr in girls, 5 yr in boys (see Chapters 20 and 535). Many children master toileting with ease, particularly once they are able to verbalize their bodily needs. For others, toilet training can involve a protracted power struggle. Refusal to defecate in the toilet or potty is relatively common and can lead to constipation and parental frustration. Defusing the issue by a temporary cessation of training (and return to diapers) often allows toilet mastery to proceed.

Implications for Parents and Pediatricians.

The normal decrease in appetite at this age often arouses worry about nutrition. For the most part, parents can be reassured that if growth is normal, the child's intake is adequate. Children normally modulate their food intake to match their somatic needs according to feelings of hunger and satiety. Daily intake fluctuates, at times widely, but intake during the period of a week is relatively stable. Parental attempts to control the child's intake interfere with this self-regulatory mechanism as the child must either accede to or rebel against the pressure. The result may be either overeating or undereating.

Motorically precocious, highly active children face increased risks of injury. Parents of such children benefit from early guidance about the need for childproofing the home, constant supervision, and bicycle helmet use (beginning with the tricycle). Parental concerns about possible hyperactivity may reflect inappropriate expectations, heightened fears, or true overactivity. Children who engage in reckless, uncontrollable activity with no apparent regard for personal safety need a safe environment with close supervision. This pattern of indiscriminate activity is sometimes seen among children who have suffered abuse or neglect.

LANGUAGE, COGNITION, AND PLAY

These three domains all involve the symbolic function, a mode of dealing with the world that emerges during the preschool period.

Language.

Language development occurs most rapidly between 2 and 5 yr of age. Vocabulary increases from 50–100 words to more than 2,000. Sentence structure advances from telegraphic phrases (“Baby cry”) to sentences incorporating all of the major grammatical components. As a rule of thumb, between age 2 and 5 yr, the number of words in a typical sentence equals the child's age (2 by age 2 yr, 3 by age 3 yr, and so on.) By 2½ yr, most children are using possessives (“My ball”), progressives (the “ing” construction, as in “I playing”), questions, and negatives. By 4 yr of age, they can count to 4 and use the past tense; by 5 yr, they can use the future tense.

It is important to distinguish between speech (the production of intelligible sounds) and language, which refers to the underlying mental act. Language includes both expressive and receptive functions. Receptive language (understanding) varies less in its rate of acquisition than does expressive language and therefore has greater prognostic importance. Language assessment is described more fully in Chapters 16 and 29 .

Language acquisition depends critically on environmental input. Key determinants include the amount and variety of speech directed toward children and the frequency with which

adults ask questions and encourage verbalization. Striking differences in these parameters between upper- and lower-class parents parallel class-related disparities in preschool language development and later school achievement.

Although experience influences the rate of language development, many linguists believe that the basic mechanism for language learning is “hard-wired” in the brain. Children do not simply imitate adult speech. Rather, they abstract the complex rules of grammar from the ambient language, generating implicit hypotheses. Evidence for the existence of such implicit rules comes from analysis of grammatical errors, such as the overgeneralized use of “s” to signify the plural and “ed” to signify the past (e.g., “We seed lots of mouses”). Children have an inborn propensity to create language. For example, deaf orphans raised by nonsigning adults were observed to invent their own sign language, including all of the essential grammar.

Language is a critical barometer of both cognitive and emotional development. Mental retardation may first become apparent with delayed speech at approximately 2 yr. Child abuse and neglect are correlated with delayed language, particularly the ability to convey emotional states. Language plays a critical part in the regulation of behavior through internalized “private speech” in which a child repeats adult prohibitions first audibly and then mentally. Language also allows children to express feelings, such as anger or frustration, without acting them out; consequently, language-delayed children show higher rates of tantrums and other externalizing behaviors.

Preschool language development lays the foundation for later success in school. Approximately 35% of U.S. children may enter school lacking the language skills that are the prerequisites of literacy acquisition. Although children typically learn to read and write in elementary school, critical foundations for literacy are established during the preschool years. Through repeated early exposure to written words, children learn about the uses of writing (telling stories or sending messages) and about its form (left to right, top to bottom). Early errors in writing, like errors in speaking, reveal that literacy acquisition is an active process involving hypothesis generation and revision. One hypothesis is that words that take longer to say (“big words”) have more letters in them regardless of what the letters are. At a later stage, letters may be assigned one to a syllable, such as GNYS to spell “genius.”

Picture books have a special role not only in familiarizing young children with the printed word but also in the development of verbal language. Reading aloud with a young child is an interactive process in which a parent focuses the child's attention on a particular picture, requests a response (by asking, “What's that?”), and then

gives the child feedback (“Right, it's a dog.”). This question-feedback routine is repeated many times in the course of reading a book. As a child's sophistication grows, the parent increases the complexity of the task, requesting descriptions (“What color is the dog?”) and later projections (“What's that dog going to do?”). The elements of shared attention, active participation, immediate feedback, repetition, and graduated difficulty make such routines ideal for language learning.

The period of rapid language acquisition is also when *developmental dysfluency* and *stuttering* are most likely to emerge. Common difficulties (in about 5% of children) include pauses and repetitions of initial sounds. Stress or excitement exacerbates these difficulties, which generally resolve on their own. About 1% of children continue to have significant stuttering. Indications for referral include whole-word or part-word repetitions, sound prolongations, word blockages, facial tension, avoidance of talking, and persistence of stuttering for longer than 6 mo. Treatment involves guidance to parents to reduce pressures associated with speaking. Specific therapeutic approaches, e.g., use of metronomes, single-syllable speaking, and electronic devices that modify auditory feedback to the child, are controversial.

Cognition.

The preschool period corresponds to Piaget's preoperational (prelogical) stage, characterized by magical thinking, egocentrism, and thinking that is dominated by perception (see Table 7–2). Magical thinking includes a confusion of coincidence for causality, animism (attributing motivations to inanimate objects and events), and unrealistic beliefs about the power of wishes. A child might believe that people cause it to rain by carrying umbrellas, that the sun goes down because it is tired, or that feeling resentment toward a sibling can actually make that sibling sick. Egocentrism refers to a child's inability to take another's point of view and does not connote selfishness. For example, a child might try to comfort an upset adult by bringing a favorite stuffed animal.

Piaget demonstrated the dominance of perception over logic by a famous series of so-called conservation experiments. In one, water is poured back and forth from a tall, thin vase to a low, wide dish and children are asked which container has more water. Invariably, they choose the one that looks larger (usually the tall vase), even when the examiner points out that no water has been added or taken away. Such misunderstandings reflect young children's developing hypotheses about the nature of the world as well as their difficulty in attending simultaneously to multiple aspects of a situation.

Play.

During the preschool period, play is marked by increasing complexity and imagination, from simple scripts replicating common experiences such as shopping and putting baby to bed (2 or 3 yr of age) to more extended scenarios involving singular events such as going to the zoo or going on a trip (3 or 4 yr of age) to the creation of scenarios that have only been imagined, such as flying to the moon (4 or 5 yr of age). A similar progression in socialization moves from minimal social interaction with peers during play (solo or parallel play, 1 or 2 yr of age) to cooperative play such as building a tower of blocks together (3 or 4 yr of age) to organized group play with distinct role assignments, as in playing house. Play also becomes increasingly rule governed, from early rules about asking (rather than taking) and sharing (2 or 3 yr of age) to rules that change from moment to moment according to the desires of the players (4 and 5 yr of age) to the beginning of the recognition of rules as relatively immutable (5 yr of age and beyond).

Play allows children to experience mastery by solving puzzles, practicing adult roles, assuming the aggressor role rather than the victim (spanking a doll), taking on superpowers (dinosaur and superhero play), and obtaining things that are denied in real life (a make-believe friend or stuffed pet). Creativity, inherent in all play, is particularly apparent in drawing, painting, and other artistic activities. The 4 yr old who chooses to let a big circle with sticks represent a body and limbs knows that real bodies do not actually look like that. The simplicity of the drawing is, at least in part, a matter of choice. Themes and emotions that emerge in a child's drawings often reflect the emotional issues of greatest importance for the child.

Moral thinking mirrors and is constrained by a child's cognitive level. Empathic responses to others' distress arise during the 2nd yr of life, but the ability to cognitively consider another child's point of view remains limited throughout the preschool period. In keeping with a child's inability to focus on more than one aspect of a situation at a time, fairness is taken to mean equal treatment regardless of circumstantial differences. Rules tend to be absolute, with guilt assigned for bad outcomes regardless of intentions.

Implications for Parents and Pediatricians.

The significance of language as a target for assessment and intervention cannot be overestimated because of its central role as an indicator of cognitive and emotional development and as a key factor in behavioral regulation and later school success. Detection and assessment of language delays, a critical part of preventive care, is discussed in Chapters 16 and 29 . Parents can support emotional development

Data used in creating the 2000 Centers for Disease Control (CDC) growth charts, as described in For each age, stature appears above weight. English units appear in parentheses, to the right of th corresponding metric units. Data for additional age points and 3rd and 97th percentiles are availab www.edc.gov/nchs, along with technical reports.

by using words that describe the child's feeling states (“You sound angry right now”) and by urging the child to use words to express feelings rather than acting out the feelings.

Parents should have a regular time each day for reading or looking at books with their children. Programs in which pediatricians give out picture books along with appropriate guidance during primary care visits have been effective in increasing reading aloud and thereby promoting language development, particularly in lower income families.

Preoperational thinking constrains how children understand experiences of illness and treatment. Many children perceive needles as huge objects that threaten to puncture them like a balloon. Verbal explanation is often not as reassuring as giving the child an opportunity to administer make-believe shots to a doll and see, repeatedly, that nothing horrible happens. Explanations that involve several contradictory aspects (“This will hurt a little, but it will keep you from getting sick”) will be lost on most preoperational children; the immediate presence of a calm parent is more comforting. Children with precocious language development may elicit overly complex explanations from adults who assume incorrectly that their cognitive sophistication matches their verbal skill.

The imaginative intensity that fuels play and the magical, animist thinking characteristic of preoperational cognition can also generate intense fears. More than 80% of parents report at least one fear in their preschool children, and nearly 50% report

TABLE 12-2 -- **Body Mass Index (BMI) Percentiles for Age, Boys and Girls, 2–20 yr**

Boys: Percentiles

Age (Yr)	*5th*	*10th*	*25th*	*50th*	*75th*	*85th*	*90th*	*95th*

Data used in creating the 2000 Centers for Disease Control (CDC) growth charts, as described in Chapter 15 . Data apply to the age range, including the listed age and subsequent month (i.e., "1 mo" represents the average for 1 mo, 0 days through 1 mo, 30 days). Data for additional age points and 3rd and 97th percentiles are available at www.cdc.gov/nchs, along with technical reports.

seven or more fears. Refusal to take baths or to sit on the toilet may arise from the fear of being washed or flushed down, reflecting a child's immature appreciation of relative size. Attempts to demonstrate rationally that there are no monsters in the closet often fail, inasmuch as the fear arises from prerational thinking, but parents may be able to reassure their children that they can ward off the monsters with "monster spray" or a similar appeal to magical thinking. In general, children's willingness to believe that their parents are large and powerful helps parents provide a sense of safety as children's world view expands.

EMOTIONAL DEVELOPMENT

Emotional challenges facing preschool children include accepting limits while maintaining a sense of self-direction, reining in aggressive and sexual impulses, and interacting with a widening circle of adults and peers. At 2 yr of age, behavioral limits are predominantly external; by 5 yr of age, these controls need to be internalized if a child is to function in a typical classroom. Success in achieving this goal relies on prior emotional development, particularly the ability to use internalized images of trusted adults to provide security in times of stress. Children need to believe themselves worthy of adult approval to be willing to work for it.

Children learn what behaviors are acceptable and how much power they wield vis-à-vis important adults by testing limits. Testing increases when it elicits an exceptional amount of attention, even though that attention is often negative, and when limits are inconsistent. Testing often arouses parental anger or inappropriate solicitude as a child's struggle to separate gives rise to a corresponding challenge for the parents: letting go. Excessively tight limits can undermine a child's sense of initiative, whereas overly loose limits can provoke anxiety in a child who feels that no

one is in control.

Control is a central issue. Young children cannot control many aspects of their life—where they go, how long they stay, what they take home from the store. They are also prone to lose internal control as well, that is, to have *temper tantrums*. When a parent occasionally gives in to a child's demands, intermittently reinforcing the tantrum behavior, tantrums can become an entrenched strategy for exerting control. Fear, overtiredness, or physical discomfort also evoke tantrums. Tantrums normally appear toward the end of the 1st yr of life and peak in prevalence between 2 and 4 yr of age. Tantrums lasting more than 15?min or regularly occurring more than three times a day may reflect underlying medical, emotional, or social problems. Frequent tantrums after 5 yr of age tend to persist throughout childhood.

Preschool children normally experience complicated feelings toward their parents that can include possessiveness toward one parent, jealousy and resentment of the other parent, and fear that these negative feelings might lead to abandonment. These emotions, most beyond a child's ability to comprehend or verbalize, often find expression in highly labile moods. The resolution of this crisis (a process extending over years) involves a child's unspoken decision to emulate the parents rather than compete with them. Play and language foster the development of emotional controls by allowing children to express emotions and to enjoy gratifications (such as being big and powerful) that are taboo in real life.

Curiosity about genitals and adult sexual organs is normal, as is masturbation. *Masturbation* that has a compulsive quality or that interferes with a child's normal activities, acting out of sexual intercourse in doll play or with other children, extreme modesty, or mimicry of adult seductive behavior all suggest the possibility of sexual abuse. Modesty appears gradually between 4 and 6 yr of age, with wide variations among cultures and families.

Implications for Parents and Pediatricians.

Most parents find it difficult to understand their preschool children at least some of the time. Rapid shifts between clinging dependence and defiant independence, between sophisticated-sounding language and infantile helplessness, and between angelic joy and uncontrollable rage can erode parents' self-confidence and patience. Guidance emphasizing appropriate expectations for behavioral and emotional development and acknowledging normal parental feelings of anger, guilt, and confusion can help lessen parents' worries both about their children and about themselves. Many parents fail to raise such concerns during pediatric visits because they feel embarrassed or because they do not think the pediatrician can help. Pediatricians need to let parents know that the child's behavior and the parents' reactions are appropriate topics for discussion.

It may be difficult to decide whether a particular child's behavior is normally challenging or indicative of a true problem. Red flags include parents who do not volunteer any positive statements about their children, evidence of threatening or overtly punitive discipline, and the existence of problems (especially tantrums) in daycare or preschool, where most preschool children manage to maintain self-control. The presence of chronic medical problems, developmental delays, or unusual family stresses signal the need for more detailed assessment. Even apparently normal behavior constitutes a problem if it arouses sufficient parental concern. An extended visit devoted to the issue or referral to a mental health professional is appropriate. Reference to *The Classification of Child and Adolescent Mental Diagnoses in Primary Care: Diagnostic and Statistical Manual for Primary Care (DSM-PC)* will help pediatricians distinguish among normal variations, problems, and disorders that may merit referral.

Corporal punishment is accepted in many traditional cultures but may be inappropriate in the modern context in which most families now live (also see Chapter 5). No evidence shows that spanking per se is harmful, but regular use of corporal punishment may reflect an excessive desire for control, as well as a lack of other parenting techniques. Parents usually claim that they do not like spanking but feel that nothing else works. Pediatricians can point out that the spanking is not working either, or it would not have to be used so often. As children habituate to repeated spanking, parents have to spank ever harder to get the desired response, increasing the risk of serious injury. Sufficiently harsh punishment may inhibit undesired behaviors, but at great psychologic cost. Children mimic the corporal punishment they receive, and it is not uncommon for preschool-age children to strike their parents back. Parents may be helped to renounce spanking or at least reserve it for extreme circumstances if they learn more effective discipline techniques, including consistent limit-setting, clear communication, and frequent approval. Time-out for approximately 1?min per year of age is a form of noncorporal punishment backed by extensive research. Parents may require detailed instruction to use time-out effectively.

Chapter 13 - Middle Childhood

During middle childhood (6–12 yr), children increasingly separate from parents and seek acceptance from teachers and other adults, and from peers. *Self-esteem* becomes a central issue, as children develop the cognitive ability to consider at the same time their own self-evaluations and their perception of how others see them. For the first time, they are judged according to their ability to produce socially valued outputs, such as good grades or home runs. This focus on accomplishment leads to the central psychosocial issue of this period, as described by Erikson, the crisis between industry and inferiority. Pressure to conform to the style and ideals of the group can be intense, and children who are different, physically or intellectually, are at risk for social isolation and depression.

PHYSICAL DEVELOPMENT

Growth during the period averages 3–3.5?kg (7?lb) and 6?cm (2.5?in) per year (see Figs. 11–1 and 11–2 and Table 12–1). Growth occurs discontinuously, in 3 to 6 irregularly timed spurts each year, each growth spurt lasting on average 8 wk. The head grows only 2–3?cm in circumference throughout the entire period, reflecting slower brain growth than before; myelinization is complete by 7 yr of age. Body habitus (endomorphic, mesomorphic, or ectomorphic) tends to remain relatively stable throughout middle childhood.

Growth of the midface and lower face occurs gradually. Loss of deciduous (baby) teeth is a more dramatic sign of maturation, beginning after eruption of the 1st molars around age 6 yr. Replacement with adult teeth occurs at a rate of about 4/yr. Lymphoid tissues hypertrophy, often giving rise to impressive tonsils and adenoids, which may require surgical removal.

Muscular strength, coordination, and stamina increase progressively, as does the ability to perform complex movements such as dancing, shooting basketballs, or playing the piano. Such higher order motor skills are a result of both maturation and training; the degree of accomplishment reflects wide variability in innate skill, interest, and opportunity. Epidemiologic studies report a general decline in physical fitness among school-age children over the past 15–20 yr. Sedentary habits at this age are associated with increased lifetime risk of obesity and cardiovascular disease.

The sexual organs remain physically immature, but interest in gender differences and sexual behavior remains active in many children and increases progressively

until puberty. Masturbation is common, if not universal. In more permissive cultures, sexual experimentation often occurs among prepubertal children.

Implications for Parents and Pediatricians.

“Normality” encompasses a wide range of physical sizes, shapes, and abilities in school-age children. Just as importantly, children's feelings about their physical attributes range from pride to shame to apparent nonchalance. Fears of being “defective” can lead to avoidance of situations in which physical differences might be revealed, such as gym class or medical examinations. Children with actual physical disabilities may face special stresses because of their difference. Medical, social, and psychologic risks tend to aggregate in children; multisystem problems are the rule rather than the exception among children at risk for long-term morbidity. The routine physical examination provides an opportunity to elicit concerns and allay fears.

Girls, in particular, often worry that they are overweight, and many engage in unhealthy dieting to achieve an abnormally thin cultural ideal. Shortness, particularly in boys, may be associated with decreased educational attainment and increased risks for behavior problems (although social class remains a more powerful predictor). The availability of recombinant human growth hormone raises the possibility of medical treatment for short children even in the absence of documented hormone deficiency. The decision to treat, with its attendant cost and discomfort, needs to be made in view of the meaning of shortness for the individual child (see Chapter 551).

A child's physical appearance may also evoke strong feelings in parents, leading them to undermine the child's self-esteem inadvertently, or, alternatively, to encourage vanity. Pediatricians can help parents distinguish between true health risks and individual variations that should be accepted. Questions about regular physical activities should be part of the medical history for health supervision visits. Participation in organized *sports* can foster skill, teamwork, and fitness, but excessive pressure to compete often has negative effects. Prepubertal children should not engage in high-stress, high-impact sports such as power lifting or football because skeletal immaturity increases the risk of injury.

COGNITIVE AND LANGUAGE DEVELOPMENT

The thinking of early elementary school-aged children differs qualitatively from that of children just 1 or 2 yr younger. In place of magical, egocentric, and perception-bound cognition, school-aged children increasingly apply rules based on observable phenomena, factor in multiple dimensions and points of view, and interpret their perceptions in view of realistic theories about physical laws. This shift from “preoperational” to “concrete logical operations” was documented by Piaget in a series of “conservation” experiments (see Chapter 12). For example, 5-yr-olds who watch a ball of clay being rolled into a snake might insist that the snake has “more” because it is longer. Seven-year-olds typically reply that the ball and snake must weigh the same because nothing has been added or taken away or because the snake is both longer and thinner. This cognitive reorganization occurs at different rates in different contexts. In the context of social interactions with siblings, young children often demonstrate an ability to understand alternate points of view long before they demonstrate that ability in their thinking about the physical world.

School makes increasing cognitive demands. Mastery of the elementary curriculum requires that a large number of perceptual, cognitive, and language processes work efficiently (Table 13–1). Attention and receptive language affect each other as well as every other aspect of learning. One cannot attend to what one cannot understand or understand without first paying attention. By third grade, children need to be able to sustain attention through a 45-min period.

The first 2 yr of elementary school are devoted to acquiring the fundamentals: reading, writing, and basic mathematics skills. By third or fourth grade, the curriculum requires that children use those fundamentals to learn increasingly complex materials. The goal of reading a paragraph is no longer to decode the words but to understand the content; the goal of writing is no longer spelling or penmanship but composition. The volume of work increases along with the complexity. Children can meet these demands only if they have mastered the basic skills to the point that their execution has become automatic. Children who have to think about how to shape each letter or who have to recalculate basic mathematics facts each time they attempt to solve a word problem fall behind.

Cognitive abilities interact with a wide array of attitudinal and emotional factors in determining classroom performance. A partial list of such factors includes eagerness to please adults, cooperativeness, competitiveness, willingness to work for a delayed reward, belief in one's abilities, and ability to risk trying when success is not ensured. Success predisposes to success, whereas failure undercuts a child's ability to take cognitive-emotional risks in the future.

TABLE 13-1 -- **Selected Perceptual, Cognitive, and Language Processes Required for Elementary School Success**

Process	Description	Associated Problems
Perceptual		
Visual analysis	Ability to break a complex figure into components and understand their spatial relationships	Persistent letter confusion (e.g., between *b*, *d*, and *g*); difficulty with basic reading and writing and limited “sight” vocabulary
Proprioception and motor control	Ability to obtain information about body position by feel and unconsciously program complex movements	Poor handwriting, requiring inordinate effort, often with overly tight pencil grasp; special difficulty with timed tasks

Phonologic processing	Ability to perceive differences between similar sounding words and to break down words into constituent sounds	Delayed receptive language skills; attention and behavior problems secondary to not understanding directions; delayed acquisition of letter-sound correlations (phonetics)
Cognitive		
Long-term memory, both storage and recall	Ability to acquire skills that are “automatic” (i.e., accessible without conscious thought)	Delayed mastery of the alphabet (reading and writing letters); slow handwriting; inability to progress beyond basic mathematics
Selective attention	Ability to attend to important stimuli and ignore distractions	Difficulty following multistep instructions, completing assignments, and behaving well; peer interaction problems
Sequencing	Ability to remember things in order; facility with time concepts	Difficulty organizing assignments, planning, spelling, and telling time
Language		
Receptive language	Ability to comprehend complex constructions, function words (e.g., if, when, only, except), nuances of speech, and extended blocks of language (e.g., paragraphs)	Difficulty following directions; wandering attention during lessons and stories; problems with reading comprehension; problems with peer relationships
Expressive language	Ability to recall required words effortlessly (word finding), to control meanings by varying position and word endings, to construct meaningful paragraphs and stories	Difficulty expressing feelings and using words for self-defense, with resulting frustration and physical acting out; struggling during “circle time” and in language-based subjects (e.g., English)

Children's intellectual activity extends beyond the classroom. Beginning in the 3rd or 4th grade, children increasingly enjoy strategy games and word play (puns and insults) that exercise growing cognitive and linguistic mastery. Many become experts on subjects of their own choosing, such as sports trivia or stamps. Others become avid readers.

Implications for Parents and Pediatricians.

Children in the cognitive stage of concrete logical operations can understand simple explanations for illnesses and necessary treatments, although they may revert to prelogical thinking under stress (as may adults). A child with pneumonia may be able to explain about white cells fighting the “germs” in the lungs but still secretly harbor the belief that the sickness is a punishment for disobedience.

Academic and classroom behavior problems, like fever, are symptoms that require diagnosis. Among the broad range of possible causes are deficits in specific cognitive, perceptual, or linguistic functions (specific learning disabilities); global cognitive delay (mental retardation); primary attention deficit; and attention deficits secondary to emotional preoccupation, depression, anxiety, or any chronic illness. Commonly, the cause is a combination of several such factors. Assessment of school problems is discussed in Chapters 16 and 29 .

Remedial approaches depend on the underlying problem or problems. Children who are inattentive because of receptive language disability will benefit more from language therapy than from stimulant medication. Similarly, psychotherapy is generally less helpful for primary attention deficits than are medication and environmental modifications aimed at increasing structure and decreasing distractions. Simply having a child repeat a failed grade rarely has any beneficial effect and often seriously undercuts the child's self-esteem. See Chapter 29 for a further discussion of learning and behavior problems. Interventions that allow children to exercise their strengths and experience success have beneficial effects that often spill over into problem areas. Educational approaches that value a wide range of talents (“multiple intelligences”) beyond the traditional ones of reading, writing, and mathematics promise to allow more children to succeed.

SOCIAL AND EMOTIONAL DEVELOPMENT

Social and emotional development proceeds in three contexts: the home, the school, and the neighborhood. Of these, the home remains the most influential. The parent-child relationship continues to provide a secure base from which children can venture forth. Milestones of a school child's increasing independence include the first sleepover at a friend's house and the first time at overnight camp. Parents should make demands for effort in school and extracurricular activities, celebrate successes, and offer unconditional acceptance when failures occur. Regular chores provide an opportunity for children to contribute to the family in a meaningful way, supporting self-esteem. Siblings have critical roles as competitors, loyal supporters, and role models. Sibling relationships exert lasting effects on personality development, influencing an individual's self-image, approach to conflict resolution, interests, and even career choices.

The beginning of school coincides with a child's further separation from the family and the increasing importance of teacher and peer relationships. In addition to friendships that may persist for months or years, experience with a large number of superficial friendships and antagonisms contributes to a child's growing social competence. Popularity, a central ingredient of self-esteem, may be won through possessions (having the right toys or the right clothes) as well as through personal attractiveness, accomplishments, and actual social skills.

Conformity is rewarded. Some children conform readily and enjoy easy social success; those who adopt individualistic styles or have visible differences may be stigmatized as “weird.” Such children may be painfully aware that they are different, or they may be puzzled by their lack of popularity. Children with social skills deficits may go to extreme lengths to win acceptance, only to meet with repeated failure. Attributions conferred by peers, such as funny, stupid, bad, or scary, may become

incorporated into a child's self-image. The peer group exerts a profound influence on the child's personality, often including mannerisms, speaking accent, aspirations, and relationship to the law. Parents may have their greatest effect indirectly, through actions that change the peer group (e.g., moving to a new community, or insisting on involvement in structured after-school activities).

In the neighborhood, real dangers such as busy streets, bullies, and strangers tax school-aged children's common sense and resourcefulness. Interactions with peers without close adult supervision call on increasing conflict resolution or pugilistic skills. Observation of older children and adults as well as advertisements in store windows and on television expose children to adult materialism, sexuality, and violence. Many of these experiences reinforce children's feeling of powerlessness in the larger

world. Compensatory fantasies of being powerful may fuel the fascination with superheroes. Hero worship and adoption of adult-like dress and mannerisms are “dress rehearsals” for adult roles and represent ways of appropriating adult power. A balance between fantasy and appropriate ability to negotiate real world challenges indicates healthy emotional development.

Implications for Parents and Pediatricians.

Children need unconditional support as well as realistic demands as they venture into a world that is often frightening. Children who show unusual difficulty in separating from parents and in facing school and neighborhood challenges may be reacting to their parents' difficulty letting them go. Other parents exert excessive pressure on their children to adopt adult behaviors and achieve academic or competitive success. Children who struggle to meet such expectations may develop behavior problems or somatic symptoms such as headaches or stomachaches as a result (Chapter 19).

Many children face stressors that exceed the normal challenges of separation and “making it” in school and neighborhood. Divorce affects nearly 50% of children. Violence between parents, parental substance abuse, and other mental health problems may also impair a child's ability to use home as a secure base for refueling emotional energies. In many neighborhoods, the threats of gangs and random violence make the normal development of independence extremely dangerous. Children in late elementary and middle school may join gangs as a means of self-protection and a way to appropriate power and belong to a cohesive group. The high prevalence of adjustment disorders among school-aged children attests to the effects of such overwhelming stressors on development.

Pediatricians need to be alert to children's functioning in all contexts (home, school, neighborhood) and consider how each of those environments either supports or overwhelms the child's ability to adapt and grow. Use of the HEADSS mnemonic—*H*ome, *E*ducation and employment, peer *A*ctivities, *D*rugs, *S*exuality, and *S*uicide or depression can help. Originally designed for adolescents, with minor modifications it also works well for school-aged children.

Chapter 14 - Adolescence (See also Part XII and Chapters 555 and 556 .)

Between 10 and 20 yr of age, children undergo rapid changes in body size, shape, physiology, and psychologic and social functioning. Hormones set the developmental agenda in conjunction with social structures designed to foster the transition from childhood to adulthood.

Adolescence proceeds across three distinct periods—early, middle, and late—each marked by a characteristic set of salient biologic, psychologic, and social issues (Table 14–1). However, individual variation is substantial, both in terms of the timing of somatic changes and the quality of the adolescent's experience. Gender and subculture profoundly affect the developmental course, as do physical and social stressors such as cerebral palsy or parental alcoholism.

EARLY ADOLESCENCE

Biologic Development.

Adrenal production of androgen (chiefly dehydroepiandrosterone sulfate [DHEAS]) may occur as early as 6 yr of age, with development of underarm odor and faint genital hair (adrenarche). Levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) rise progressively throughout middle childhood without dramatic effect. The rapid changes of puberty begin with increased sensitivity of the pituitary to gonadotropin-releasing hormone (GnRH), pulsatile release of GnRH, LH, and FSH during sleep, and corresponding increases in gonadal androgens and estrogens. The triggers for these changes are incompletely understood, but may involve neuronal development that is ongoing throughout middle childhood and adolescence. Contemporary children in the United States may enter puberty earlier than the published norms (although reports of dramatically earlier puberty are controversial), perhaps related to increased weight and adiposity. The resulting sequence of somatic and physiologic changes gives rise to the sexual maturity rating (SMR) or Tanner stages. Figures 14–1 and 14–2 depict the somatic changes used in the SMR scale; Tables 14–2 and 14–3 describe these changes in words. Table 14–4 lists median ages and

Figure 14-1 Sex maturity ratings of pubic hair changes in adolescent boys and girls. (Courtesy of JM Tanner, MD, Institute of Child Health, Department of Growth and Development, University of London, London, England.)

TABLE 14-1 -- Central Issues in Early, Middle, and Late Adolescence

Variable	Early Adolescence	Middle Adolescence	Late Adolescence
Age (yr)	10–13	14–16	17–20 and beyond
SMR*	1–2	3–5	5
Somatic	Secondary sex characteristics; beginning of rapid growth; awkward	Height growth peaks; body shape and composition change; acne and odor; menarche; spermarche	Slower growth
Sexual	Sexual interest usually exceeds sexual activity	Sexual drive surges; experimentation; questions of sexual orientation	Consolidation of sexual identity
Cognitive and moral	Concrete operations; conventional morality	Emergence of abstract thought; questioning mores; self-centered	Idealism; absolutism
Self-concept	Preoccupation with changing body; self-consciousness	Concern with attractiveness, increasing introspection	Relatively stable body image
Family	Bids for increased independence; ambivalence	Continued struggle for acceptance of greater autonomy	Practical independence; family remains secure base
Peers	Same-sex groups; conformity; cliques	Dating; peer groups less important	Intimacy; possibly commitment
Relationship to society	Middle-school adjustment	Gauging skills and opportunities	Career decisions (e.g., drop out, college, work)

SMR = sexual maturity rating.

* *See text and Figures 14–1 and 14–2 .*

normal ranges for key stages of breast, pubic hair, and penile development. Note that the SMR stages are not perfectly synchronized (e.g., SMR2 penis development precedes SMR2 pubic hair by on average 1.5 years). Figures 14–3 and 14–4 depict the typical sequence of pubertal changes in males and females, respectively. The range of normal for progress through the stages of sexual maturity is wide.

In girls, the first visible sign of puberty is the appearance of breast buds, between 8

and 13 yr. Menses typically begin 2–21/2 yr later (normal range 9–16 yr), around the peak in height

Figure 14-2 Sex maturity ratings of breast changes in adolescent girls. (Courtesy of JM Tanner, MD, Institute of Child Health, Department of Growth and Development, University of London, London, England.)

velocity (see Fig. 14–4). Less obvious changes include enlargement of the ovaries, uterus, labia, and clitoris; thickening of endometrium and the vaginal mucosa; and increased vaginal glycogen, predisposing to yeast infections.

In boys, testicular enlargement begins as early as 91/2 yr. Peak growth occurs when testis volumes reach approximately 9–10?cm^3 . Under the influence of LH and testosterone, the seminiferous tubules, epididymis, seminal vesicles, and prostate enlarge. The left testis normally is lower than the right; the opposite may be true in situs inversus. Some degree of breast hypertrophy occurs in 40–65% of pubertal boys as a result of a relative excess of estrogenic stimulation. Gynecomastia sufficient to cause embarrassment and social disability occurs in fewer than 10%. Breast swelling less than 4?cm in diameter has a 90% chance of spontaneous resolution within 3 yr. For greater degrees of enlargement, hormonal or surgical treatment may be indicated. Obesity may exacerbate gynecomastia and should be addressed through diet and exercise.

For both sexes, growth acceleration begins in early adolescence, but peak growth velocities are not reached until SMR3 or 4. Boys typically peak 2–3 yr later than girls (Fig. 14–5) and continue their linear growth for approximately 2–3 yr after girls have stopped. The growth spurt begins distally, with enlargement of hands and feet followed by the arms and legs and finally by the trunk and chest. This asymmetric growth gives young adolescents a gawky look. Rapid enlargement of the larynx, pharynx, and lungs leads to changes in vocal quality, often heralded by a period of vocal instability (voice cracking) or dysphonation. Adrenal androgens stimulate the sebaceous glands, promoting the development of acne. Elongation of the optic

TABLE 14-2 -- **Classification of Sex Maturity Stages in Girls**

SMR Stage	Pubic Hair	Breasts
1	Preadolescent	Preadolescent
2	Sparse, lightly pigmented, straight, medial border of labia	Breast and papilla elevated as small mound; areolar diameter increased
3	Darker, beginning to curl, increased amount	Breast and areola enlarged, no contour separation
4	Coarse, curly, abundant but amount less than in adult	Areola and papilla form secondary mound
5	Adult feminine triangle, spread to medial surface of thighs	Mature, nipple projects, areola part of general breast contour

SMR = sexual maturity rating.

globe often results in nearsightedness. Dental changes include jaw growth, loss of the final deciduous teeth, and eruption of the permanent cuspids, premolars, and finally molars (see Table 10–6). Orthodontic appliances may be needed.

Sexuality.

Sexuality includes not only sexual behaviors but also interest and fantasies, sexual orientation, attitudes toward sex and its relationship to emotions, and awareness of socially defined roles and mores.

Interest in sex increases in early puberty. Ejaculation occurs for the first time, usually during masturbation and later spontaneously in sleep. Some boys worry that these emissions are signs of infection. Early adolescents sometimes masturbate socially; mutual sexual exploration is not necessarily a sign of homosexuality (Chapter 26). Sexual behavior, other than masturbation, is less common in early puberty, although 31% of an urban sample reported sexual intercourse before 14 yr of age.

The relationship between hormonal changes and sexual interest and activity is controversial; no consistent links between hormones and sexual arousal, age of first intercourse, or frequency of intercourse have been found.

Cognitive and Moral Development.

In piagetian theory, adolescence marks the transition from the concrete operational thinking

Figure 14-3 Sequence of maturational events in males. (Adapted from Marshall WA, Tanner JM: Variations in the pattern of pubertal changes in boys. *Arch Dis Child* 1970;45:13.)

TABLE 14-4 -- Variability in Timing of Sexual Maturation

SMR	Early (mean - 2 SD Early)	Average (median)	Late (mean + 2 SD Late)
Timing of SMR Stages in Girls			
Pubic Hair			
SMR2	9.0	11.2	13.5
SMR3	9.6	11.9	14.1
SMR4	10.3	12.6	14.8
Breast Development			
SMR2	8.9	10.9	12.9
SMR3	9.8	11.9	13.9
SMR4	10.5	12.9	15.3
Timing of SMR Stages in Boys			
Pubic Hair			
SMR2	9.9	12.0	14.1
SMR3	11.2	13.1	14.9
SMR4	12.0	13.9	15.7
Penis Development			
SMR2	9.2	10.5	13.7
SMR3	10.1	12.4	14.6
SMR4	11.2	13.2	15.4

SMR = sexual maturity rating; SD = Standard deviation.

Data fromTanner JM, Davies PSW: Clinical longitudinal standards for height and height velocity for North American children. J Pediatr 1985; 107:317.

characteristic of school-aged children (Chapter 13) to formal logical operations. Formal operations include the ability to manipulate abstractions such as algebraic expressions, to reason from known principles, to weigh many points of view according to varying criteria, and to think about the process of thinking itself. Some early adolescents demonstrate formal thinking, others acquire the capability later, and others do not ever fully acquire it. Young adolescents may be able to apply formal operations to schoolwork but not to personal dilemmas. When the emotional stakes are high, magical thinking, such as the conviction of invulnerability, may interfere with higher order cognition. The ability to treat possibilities as real entities may affect critical decisions, such as whether or not to have unprotected intercourse or engage in other risk-taking behavior.

Some theorists argue that the transition from concrete to formal operations follows from quantitative increases in knowledge, experience, and cognitive efficiency rather than a qualitative reorganization of thinking. Consistent with this view are data showing a steady rise in cognitive processing speed from late childhood through early adulthood, associated with a reduction in synaptic number (pruning of less-used pathways) and progressive maturation of electroencephalographic results.

Figure 14-4 Sequence of maturational events in females. (Adapted from Marshall WA, Tanner JM: Variations in pattern of pubertal changes in girls. *Arch Dis Child* 1969;44:291.)

TABLE 14-5 -- **Modal Age at Onset and Completion of Fusion in Skeletal Areas in Adolescence**

Boys: Modal Age Between (yr)	Area	Girls: Modal Age Between (yr)
	Elbow	
13.0–13.5	Onset in humerus	11.0–11.5
15.0–15.5	Complete in ulna	12.5–13.0
	Foot and Ankle	
14.0–14.5	Onset in great toe	12.5–13.0
15.5–16	Complete in tibia, fibula	14.0–14.5
	Hand and Wrist	
15.0–15.5	Onset in distal phalanges	13.0–13.5
17.5–18.0	Complete in radius	16.0–16.5
	Knee	
15.0–15.5	Onset in tibial tuberosity	13.5–14.0
17.5–18.0	Complete in fibula	16.0–16.5
	Hip and Pelvis	
15.5–16.0	Onset in greater trochanter	14.0–14.5
after 18.0	Complete in symphysis	17.5–18.0
	Shoulder and Clavicle	
15.5–16.0	Onset in greater tubercle of humerus	14.0–14.5
after 18.0	Complete in clavicle	17.5–18.0

It is unclear whether or not the hormonal changes of puberty directly affect cognitive development.

The development of moral thinking roughly parallels general cognitive development. Most preadolescents perceive right and wrong as absolute and unquestionable. Taking a loaf of bread to feed a starving child is wrong because it is “stealing.” Adolescents often question received morality, embracing the behavior standards of the peer group. Group membership may allow them to avoid guilt feelings for perceived moral infractions by shifting responsibility from themselves to the group.

Self-Concept.

Self-consciousness increases exponentially in response to the somatic transformations of puberty. Self-awareness at this age tends to center on external characteristics in contrast to the introspection of later adolescence. It is normal for early adolescents to scrutinize their appearance and to feel that everyone else is staring at them too. Girls, in particular, are at risk for viewing themselves as overweight. Dieting behavior is common, and girls who rate themselves as fat/out of shape may be at increased risk of depression (Chapter 23). Severe body image distortions, such as anorexia nervosa, also tend to appear at this age (Chapter 104). There is controversy about whether puberty may increase self-esteem in boys but undermine it in girls as both sexes assume gender roles that incorporate societal inequalities in power and prestige.

Relationships with Family, Peers, and Society.

In early adolescence, the trend toward separation from family with increasing involvement in peer activities accelerates. A symbolic expression of this shift is the renunciation of family norms of dress and grooming in favor of the peer group “uniform.” Such stylistic changes frequently spark conflicts that are truly about power or difficulty accepting separation. Not all adolescents rebel, and not all parents reject such assertions of separateness as signs of insurrection. Most adolescents continue to strive to please their parents even while they disagree on certain issues.

Separation from family often involves selecting adults outside of the family as role models and developing close relationships with particular teachers or the parents of other children. Organizations such as scouting, sports teams, or gangs provide an important sense of extra-familial belonging.

Figure 14-5 Height velocity curves for U.S. boys *(solid line)* and girls *(dashed line)* who have their

peak height velocity at the average age (i.e., average growth tempo). (From Tanner JM, Davies PSW: Clinical longitudinal standards for height and height velocity for North American children. *J Pediatr* 1985;107: 317.)

Early adolescents often socialize in same-sex peer groups. Scatological jokes, teasing directed against the other gender, and rumor mongering about who likes whom attest to burgeoning sexual interest. Belonging is all important. In one-to-one friendships, boys and girls may differ in important ways. Female friendships may center on sharing confidences, whereas male relationships may focus more on shared activities and competition.

An early adolescent's relationship to society centers on school. The shift from elementary to junior high school entails giving up the protection of the homeroom in exchange for the additional stimulation and responsibility involved in moving from class to class. This change in school structure mirrors and reinforces the changes involved in separating from the family.

The societal preoccupation with youth and sexuality generates constant exposure to sexually suggestive and explicit images. At the same time, reliable information about sexuality in general, and contraception in particular, remains sparse. Ready access to pornography on the Internet may increase the risk of premature sexual activity or exploitation.

Implications for Parents and Pediatricians.

Physical growth, body preoccupation, and sexual interest correlate with sexual maturity, whereas cognitive advancement, separation, and changes in social behavior may correlate more closely with chronological age or grade in school. Discordance between chronological age and sexual maturation may increase the stress of early adolescence. As a group, early maturing boys enjoy greater social success and higher self-esteem than do those who mature later. For girls, by contrast, early maturation is associated with poorer school performance and lower self-esteem.

Early adolescents often have questions about the somatic and sexual changes they are experiencing. Among both rural and urban adolescents, the range of sophistication is wide. During a physical examination, a pediatrician can anticipate concerns and volunteer information that the adolescent may have been too uncomfortable to request. Parents, too, may have concerns that they are hesitant to discuss. If the parent is interviewed alone, it is important that this be done first, before the interview with the child, to avoid undermining the adolescent's trust.

The adolescent's level of cognitive sophistication has implications for the sort of explanations that will be most helpful. Open-ended questions about common dilemmas facing young adolescents (e.g., whether or not to join a clique or gang or to abide by family rules that seem unjustified) can provide information about cognitive level and help assess the likelihood of risky behavior (see Chapters 5 and 17).

Parents and children often need help differentiating between the normal discomforts of the age and truly concerning behaviors. Discomfort with one's body is normal; the conviction that one is overweight and needs to diet despite objective evidence to the contrary is concerning. Bids for autonomy in the form of avoidance of family activities, demands for privacy, and increased argumentativeness are normal; extreme withdrawal or antagonism may be a sign of dysfunction. Interest in sex, sometimes heralded by the appearance of pornographic magazines, is normal; sexual intercourse in early adolescence, though fairly common, is usually a sign of developmental dysfunction. Bewilderment and dysphoria at the start of junior high school are normal; continued failure to adapt several weeks to months later suggests a more serious problem.

MIDDLE ADOLESCENCE

Biologic Development.

In middle adolescence, growth accelerates above the prepubertal rate of 6–7?cm (3?in) per year. In the average girl, the growth spurt peaks at 11.5 yr at a top velocity of 8.3?cm (3.8?in) per year and then slows to a stop at 16 yr (see Fig. 14–4). In the average boy, the growth spurt starts later, peaks at 13.5 yr at 9.5?cm (4.3?in) per year, and then slows to a stop at 18 yr. Weight gain parallels linear growth, with a delay of several months, so that adolescents seem first to stretch and then fill out. Pubertal weight gains account for approximately 40% of adult weight. Muscle mass also increases, followed several months later by an increase in strength; boys show greater gains in both. Lean body mass, approximately 80% in the average prepubertal child, increases in boys to 90% and decreases in girls to 75% as subcutaneous fat accumulates.

Bone maturation correlates closely with SMR because epiphyseal closure is under androgenic control (Table 14–5). Boys with SMR3 pubic hair and SMR4 genitals normally have their peak growth spurt ahead of them; girls at the same SMR are usually past their peaks (see Figs. 14–3 and 14–4). Widening of the shoulders in boys and of the hips in girls is also hormonally determined. Other physiologic changes include a doubling in heart size and lung vital capacity from preadolescent norms. Blood pressure, blood volume, and hematocrit rise, particularly in boys. Androgenic stimulation of sebaceous and apocrine glands results in acne and body odor. A physiologic increase in sleepiness may be mistaken for laziness.

Sexual maturation in middle adolescence is dramatic, with the achievement of menarche in 30% of girls by SMR3 (mean age 12–14 yr) and in 90% by SMR4 (mean age 13–15 yr). Menarche usually follows approximately 1 yr after the growth spurt begins. The timing of menarche, not completely understood, appears to be determined by genetics as well as such factors as adiposity, chronic illness, and exercise. In developed countries, the average age at menarche has decreased in the past century, perhaps in response to better nutrition and less physical activity. Before menarche, the uterus achieves a mature configuration, vaginal lubrication increases, and a clear vaginal discharge appears, sometimes mistaken for a sign of infection. In boys, spermarche occurs and the penis lengthens and widens.

Sexuality.

Dating becomes a normative activity during middle adolescence. The degree of sexual activity varies widely. At age 16 yr, approximately 30% of girls and 45% of boys report having sexual intercourse, whereas 17% report petting, and some 22% report kissing as the only sexual behavior.

Biologic maturation and social pressures combine to determine sexual activity. High testosterone and low religiosity together may predict which boys become sexually active. Most parents discourage sexual activity, but some actually encourage it in hopes of boosting the child's popularity or of living vicariously through the child's experiences. *Homosexual experimentation* is common and does not necessarily reflect a child's ultimate sexual orientation. Many adolescents worry that they might be homosexual, and dread being found out. As a result, homosexual dating and sexual activity during adolescence are rare. Homosexual adolescents face increased risk of isolation and depression. Fear of stigmatization may keep them from discussing their concerns with pediatricians or other potentially helpful adults (see Chapter 26).

In addition to sexual orientation, middle adolescents begin to sort out other important aspects of sexual identity, including beliefs about love, honesty, and propriety. Dating relationships are often superficial at this age, emphasizing attractiveness and sexual experimentation rather than intimacy. Adolescents tend to choose one of three sexual paths: celibacy, monogamy, or polygamous experimentation. Most have some knowledge of the risks of pregnancy, acquired immunodeficiency syndrome, and other sexually transmitted diseases, but knowledge does not consistently control behavior. A minority use any contraception at first intercourse, and fewer than 75% consistently use condoms or other effective methods.

Cognitive and Moral Development.

With the transition to formal operational thought, middle adolescents question and analyze extensively. Questioning of moral conventions fosters the development of personal codes of ethics. Such codes often appear designed to justify the adolescent's sexual appetite: “Anything I want is right.” In other cases, adolescents may embrace a code that is more strict than that of their parents, perhaps in response to the anxiety engendered by the weakening of the conventional limits. An adolescent's new flexibility of thought has pervasive effects on relationships with self and others.

Self-Concept.

The peer group exerts less influence over dress, activities, and behavior. Middle adolescents often experiment with different personae, changing styles of dress, groups of friends, and interests from month to month. Many philosophize about the meaning of their lives and wonder, “Who am I?” and “Why am I here?” Intense feelings of inner turmoil and misery are common and may be difficult to differentiate from psychiatric illness. Girls may tend to characterize themselves and their peers according to interpersonal relationships (“I am a girl with close friends”), whereas boys as a group may focus on abilities (“I am good at sports”).

Relationships with Family, Peers, and Society.

Puberty commonly results in strained relationships between adolescents and their parents. As part of separation, adolescents may become distant from parents, redirecting emotional and sexual energies toward peer relationships. Dating can become a lightning rod for parent-child battles, in which the real issue may be the fact of separation rather than the particulars of “with whom” or “how late.”

As dating increases, the need to belong to same-sex groups declines. Physical attractiveness and popularity remain critical factors in both peer relationships and self-esteem. Children with visible differences, such as cleft lip, are at risk for problems developing social skills and confidence and may have more difficulty establishing satisfying relationships.

Middle adolescents often begin thinking seriously about what they want to do as adults, a question that formerly had been comfortably hypothetical. The process involves self-assessment and assessment of the opportunities available. The presence or absence of realistic role models, as opposed to the idealized ones of earlier periods, can be crucial.

Implications for Parents and Pediatricians.

Physical and sexual maturation, changes in sexual behavior and identity, emotional distance from parents, waning peer group influence, introspection, and growing cognizance of life after childhood all combine to make middle adolescence a time when the opportunity to talk confidentially with a nonjudgmental, informed adult can be particularly appreciated and helpful.

Adolescents vary greatly in their rate of physical and social progress and in the resolution of central conflicts about autonomy and self-esteem. Questions about family and peer relationships can help locate a child along the developmental continuum and facilitate individualized counseling. In asking about dating and sex, it is important not to convey the assumption of heterosexuality because that will reduce the likelihood that concerns about sexual orientation will surface. In talking to a boy, for example, one might observe that some boys are interested sexually in girls, some boys are interested in other boys, and some are interested in both (or neither).

LATE ADOLESCENCE

Biologic Development.

The somatic changes in this period are modest by comparison. The final stages of breast, penile, and pubic hair development occur by 17–18 yr of age in 95% of males and females. Minor changes in hair distribution often continue for several years in males, including the growth of facial and chest hair and the onset of male-pattern

baldness in a few.

Psychosocial Development.

Sexual experimentation decreases as adolescents adopt more stable sexual identities. Cognition tends to be less self-centered, with increasing thoughts about concepts such as justice, patriotism, and history. Older adolescents are often idealistic but also may be absolutist and intolerant of opposing views. Religious or political groups that promise answers to complex questions may hold great appeal.

Slowing physical changes permit the emergence of a more stable body image. Intimate relationships are also an important component of identity for many older adolescents. In contrast to the often superficial dating relationships of middle adolescence, these relationships increasingly involve love and commitment. Career decisions become pressing because an adolescent's self-concept is increasingly bound up in the emerging role in society (as student, worker, or parent).

Implications for Parents and Pediatricians.

Erikson identified the crucial task of adolescence as that of establishing a stable sense of identity, including separation from family of origin, initiation of intimacy, and realistic planning for economic independence. To achieve these milestones, developmental progress is required of both adolescents and their parents. Continued difficulty in any of these areas may constitute an indication for referral for counseling.

Chapter 15 - Assessment of Growth

Growth assessment is an essential component of pediatric health surveillance because almost any problem within the physiologic, interpersonal, and social domains can adversely affect growth. The most powerful tool in growth assessment is the growth chart (see Figs. 11–1 and 11–2). Combined with an accurate scale, a length board, stadiometer, and tape measure, the growth chart provides most of the information needed to assess growth. Major concerns are undernutrition and failure to thrive, but in addition obesity is now recognized as a growing epidemic.

GROWTH CHART DERIVATION AND INTERPRETATION

In 2000, the Centers for Disease Control and Prevention (CDC) published revised growth charts, with significant improvements. The new charts contain data from five national surveys conducted between 1963 and 1994. Analyses were done to render the data representative of the United States population, both demographically and in terms of breast-feeding prevalence. Excluded from the charts are data from very low birthweight children, because their growth patterns are different, and also the most recent data for children 6 yr of age and older, so that the recent rapid increase in the prevalence of obesity would not unduly raise the upper limits of normal. Several deficiencies of the older charts have been corrected, such as the over-representation of bottle-fed infants, and the reliance on a local data set for the infant charts. The disjunction between length and height, when moving from the infant curves to those for older children, no longer exists, and z-scores (see Chapter 7) calculated from the curves now match those calculated using the standard CDC software. Most importantly, the new standard provides body mass index (BMI, see below) curves through age 20 yr, facilitating identification of obesity.

It is important to realize that the revised charts do not represent *optimal* growth, because they still incorporate data from many bottle-fed infants. Compared to the current standards, an exclusively breast-fed infant would be expected to plot higher for weight in the first 6 mo of life, but relatively lower in the 2nd half of the 1st year. Awareness of this growth difference should avoid overidentification of growth problems in breast-fed infants. The World Health Organization (WHO) is developing charts based on exclusively breast-fed infants, which will become the international standard for children up to 5 yr of age.

Caution must also be used in applying the charts to adolescents. Growth during adolescence is linked temporally to the onset of puberty, which varies widely (Chapter 14). By using cross-sectional data based on chronological age, the charts lump together subjects who are at different stages of maturation. For example, the data for 12-yr-old boys include both early-maturing boys who are at the peak of their growth spurts and later-maturing ones who are still growing at their prepubertal rate. The net result is to artifactually level off the growth peak, making it seem as though adolescent children grow more gradually and for a longer period than they do. The standard charts may indicate poor or excessive growth when a child is growing normally but happens to be a late or early maturer. Growth charts

derived from longitudinal data are recommended for adolescents, when precision is necessary.

For infants, the measure of linear growth is *length,* taken by two examiners (one to position the child) with the child supine on a measuring board. For older children, the measure is *stature,* taken with a child standing on a stadiometer. This technical difference results in children's appearing to shift down in length as they change from the younger to the older chart. The data are presented in five standard charts: (1) weight for age; (2) height (length and stature) for age; (3) head circumference for age; (4) weight for height (length and stature); and (5) BMI. Separate charts are provided for boys and girls (see Figs. 11–1 and 11–2). Charts with lines for the 3rd and 97th percentile are also available.

Each chart is composed of seven or eight percentile curves, representing the distribution of weight, length, stature, or head circumference values at each age. The percentile curve indicates the percentage of children at a given age on the *x*-axis whose measured value falls below the corresponding value on the *y*-axis. For example, on the weight chart for boys 0–36 mo of age (see Fig. 11–1*A*), the 9-mo age line intersects the 25th percentile curve at 8.6?kg, indicating that 25% of the 9-mo-old boys in the National Center for Health Statistics sample weigh less than 8.6?kg (75% weigh more). Similarly, a 9-mo-old boy weighing more than 11.2?kg is heavier than 95% of his peers.

By definition, the 50th percentile is the median, the value above (and below) which 50% of the observed values fall. It is also termed the *standard value* in the sense that the standard height for a 7-mo girl is 67?cm (see Fig. 11–1*B*). The weight-for-height charts (see Fig. 11–2) are constructed in an analogous fashion, with length or stature in place of age on the *x*-axis. According to the chart, the median or standard weight for a girl measuring 110?cm is 18.6?kg.

The numeric data on which the charts are based are presented in Tables 12–1 and 12–2 . The charts are useful because they facilitate assessment of growth over time. Specialized charts have also been developed for United States children with various conditions, including Down, Turner, and Klinefelter syndromes and achondroplasia.

ANALYSIS OF GROWTH PATTERNS

Growth is a process rather than a static quality. An infant at the 5th percentile of weight for age may be growing normally, may be failing to grow, or may be recovering from growth failure, depending on the *trajectory* of the growth curve. Typically, infants and children stay within one or two growth channels. This

canalization attests to the robust control that genes exert over body size.

A normal exception commonly occurs during the 1st 2 yr of life. For full-term infants, size at birth reflects the influence of the uterine environment; size at age 2 yr correlates with mean parental height, reflecting the influence of genes. Between birth and 18 mo, small infants often shift percentiles upward toward their parents' mean percentile. Large neonates with smaller parents often shift downward, with decelerating growth beginning at 3–6 mo and ending as an infant achieves a new growth channel at approximately 13–18 mo.

It is important to correct for various factors in plotting and interpreting growth charts. For premature infants, overdiagnosis of growth failure can be avoided by subtracting the weeks of prematurity from the postnatal age when plotting growth parameters. Very low birthweight (VLBW, <1,500?g) infants may continue to show *catch-up growth* through early school age. The presence of neurologic abnormality (e.g., cerebral palsy) in VLBW infants may limit catch-up growth. Growth standards for premature infants were published in the 1960s and recently updated (in Scandinavia).

For adolescents, normal variations in the timing of the growth spurt can lead to misdiagnosis of growth abnormalities. In general practice, cognizance of the relationship between sexual maturity and growth suffices (see Chapter 14). Special growth charts have been developed for early-, average-, and late-maturing adolescents that can be used when additional precision is needed. For children with particularly tall or short parents, there is a risk of overdiagnosing growth disorders if parental height is not taken into account or, conversely, of underdiagnosing growth disorders if parental height is accepted uncritically as the explanation. Standards have been developed to allow adjustments on the adolescent height curve based on mean parental height. These charts are based on a small, possibly nonrepresentative sample, which limits the generalizability of these standards.

The analysis of growth patterns provides critical information for the diagnosis of *failure to thrive* (FTT) (see Chapter 36). There is no universally agreed-on criterion for FTT or growth failure; most consider the diagnosis if a child's weight is below the 5th percentile or drops down more than two major percentile lines. Calculation of weight gain in grams per day, using Table 10–5 for age-related standards, allows more precise estimation of growth rate.

Weight-for-height below the 5th percentile remains the single best growth chart indicator of acute undernutrition. Children who have been chronically malnourished may be short as well as thin, so that their weight-for-height curves may appear relatively normal. Chronic, severe undernutrition in infancy can also depress head growth, an ominous predictor of later cognitive disability.

When growth parameters fall below the 5th percentile, it becomes necessary to express the values as percentages of the median or standard value. For example, a 12-mo-old girl weighing 7.1?kg is at 75% of the median weight (9.5?kg) for her age. Using the calculated percentage of standard rather than the percentile, growth failure can be graded from mild to severe according to Table 15–1 . These designations correlate with risk of mortality in developing countries; their correlation with short-and long-term sequelae of growth failure in the United States is less well documented. Another way to describe extremes of height is the *height age,* the age at which the standard (median) height equals the child's present height. A 30-mo-old child who is as tall as an average 13 mo old has a height age of 13 mo. The *weight age* is defined analogously.

Nutritional insufficiency must be differentiated from congenital, constitutional, familial, and endocrine causes of decreased linear growth (see also Chapter 42). In the latter cases, the length declines first or at the same time as the weight; weight for height is normal or elevated. In nutritional insufficiency, the weight declines before the length and the weight for height is low (unless there has been chronic stunting). Figure 15–1 depicts typical growth curves for four classes of decreased linear growth. In congenital pathologic short stature, an infant is born small and growth gradually tapers off throughout infancy. Causes include chromosomal abnormalities (Turner syndrome, trisomy 21), infection (TORCH [toxoplasmosis, other infections,

TABLE 15-1 -- **Severity of Malnutrition: Stunting and Wasting**

Grade of Malnutrition	Weight for Age* (Wasting)	Height for Age† (Stunting)	weight for Height‡
0, normal	>90	>95	>90
1, mild	75–90	90–95	81–90
2, moderate	60–74	85–89	70–80
3, severe	<60	<85	<70

Values represent percentage of median for age.

(From Mahoney CP: Evaluating the child with short stature. *Pediatr Clin North Am* 1987;34:825.)

Figure 15-2 Body mass index (BMI) percentiles for boys (*A*) and girls (*B*) age 2–20 yr. (Official Centers for Disease Control [CDC] growth charts, as described in this chapter. 85th to 95th percentile is “at risk for overweight”; >95th percentile is “overweight”; <5th percentile is “underweight.” Technical information and interpretation and management guides are available at www.cdc.gov/nchs. See also Table 12–2 .)

rubella, cytomegalovirus infection, and herpes simplex] infections), teratogens (phenytoin [Dilantin], alcohol), and extreme prematurity. In constitutional growth delay, weight and height decrease near the end of infancy, parallel the norm through middle childhood, and accelerate toward the end of adolescence. Adult size is normal. In familial short stature, both the infant and parents are small; growth runs parallel to and just below the normal curves.

Growth charts can confirm an impression of obesity if the weight for height exceeds 120% of the standard (median) weight for height. The *body mass index* (BMI) can be calculated as weight per height^2 when weight is in kilograms and height is in meters (Fig. 15–2). If measurements are made in pounds and inches, the conversion requires 2 steps: (1) convert fractions to decimals (thus, 32 ¾ lbs becomes 32.75) and (2) calculate BMI as lbs per inch^2 , then multiply by 730 (thus, a BMI of 0.031?lbs/in^2 corresponds to a BMI of 22?kg/m^2 , which can then be plotted on standard BMI tables; see Fig. 15–2). According to the CDC, a BMI over the 95th percentile indicates “overweight,” between 85th and 95th percentile is “risk of overweight,” and below the 5th percentile is “underweight.” Although widely accepted as the best clinical measure of under- and overweight, BMI may not provide an accurate index of adiposity, because it does not differentiate lean tissue and bone from fat. Measurement of triceps and subscapular skinfold thickness give a better estimate of adiposity (Fig. 15–3), although considerable experience is needed for accuracy, and variability in fat distribution may confound the measurement.

Accurate measurement of weight and length is of obvious importance. Scales should be calibrated regularly. Supine length should be measured on a board; length measurements using a tape are inaccurate. Stature is best measured using a stadiometer;

Figure 15-3 Skinfold thickness by age and sex, as measured by Harpenden skinfold calipers over triceps and under scapula. Scale is in millimeters on the left side and logarithmic transformation units on the right side. The lines shown are the 50th percentiles for British children. (From Tanner JM: *Fetus into Man: Physical Growth from Conception to Maturity.* Cambridge, MA, Harvard University Press, 1978.)

swing-arm measuring sticks attached to office scales are inaccurate. Head circumference is measured from the supraorbital ridge in front to the farthest point of the occiput in back. Cloth tapes stretch and should be avoided.

OTHER INDICES OF GROWTH

Body Proportions.

Body proportions follow a sequence of regular changes with development. The head and trunk are relatively large at birth, with progressive lengthening of the limbs throughout development, particularly during puberty (Chapter 14). Proportionality can be assessed by measuring the *lower body segment,* defined as the length from the symphysis pubis to the floor, and the *upper body segment,* defined as the height minus the lower body segment. The ratio of upper body segment divided by lower body segment (U/L ratio) equals approximately 1.7 at birth, 1.3 at 3 yr of age, and 1.0 after 7 yr of age. Higher U/L ratios are characteristic of short-limb dwarfism or bone disorders such as rickets.

Skeletal Maturation.

Reference standards for bone maturation facilitate estimation of bone age (see Tables 10–7 and 14–5). *Bone age* correlates well with stage of pubertal development and can be helpful in predicting adult height in early- or late-maturing adolescents. In familial short stature, the bone age is normal (comparable to chronological age). In constitutional delay, endocrinologic short stature, and undernutrition, the bone age is low and comparable to the height age. The most commonly used standards are those of Gruelich and Pyle, which require radiographs of the left hand and wrist; knee films are sometimes added for younger children. Sontag's method requires radiographs of each major joint on the left side of the body. A method developed by Tanner and colleagues may offer added accuracy. Skeletal maturation is linked more closely to sexual maturity rating than to chronological age. It is more rapid and less variable in girls than in boys.

Dental Development.

Dental development includes mineralization, eruption, and exfoliation (see Table 10–6). Initial mineralization begins as early as the second trimester (mean age for central incisors, 14 wk) and continues through 3 yr of age for the primary (deciduous) teeth and 25 yr of age for the permanent teeth. Mineralization begins at the crown and progresses toward the root. Mean ages for eruption of primary teeth are given in Table 10–6 . Eruption begins with the central incisors and progresses laterally. Exfoliation begins at about 6 yr of age and continues through 12 yr of age. Eruption of the permanent teeth may follow exfoliation immediately or may lag by 4–5 mo. The timing of dental development is poorly correlated with other processes of growth and maturation.

Delayed eruption is usually considered when there are no teeth by approximately 13 mo of age (mean +3 SD). Common causes include hypothyroid, hypoparathyroid, familial, and (the most common) idiopathic. Individual teeth may fail to erupt because of mechanical blockage (crowding, gum fibrosis). Causes of early exfoliation include histiocytosis X, cyclic neutropenia, trauma, and idiopathic factors. Nutritional and metabolic disturbances, prolonged illness, and certain medications (tetracycline) commonly result in discoloration or malformations of the dental enamel. A discrete line of pitting on the enamel suggests a time-limited insult.

Physiologic and Structural Growth.

Virtually every organ and physiologic process undergoes a predictable sequence of structural or functional changes, or both, during development. Reference values for developmental changes in a wide variety of systems (pituitary and renal function, electroencephalogram, electrocardiogram) have been published. Physiologic and structural changes of particular relevance to general pediatrics include the following:

1. Respiratory rate and pulse rate decrease sharply during the first 2 yr and then more gradually throughout childhood; blood pressure rises steadily beginning at approximately 6 yr of age (Chapters 356 and 415).
2. Development of the paranasal sinuses continues throughout childhood. The ethmoids, maxillary, and sphenoid sinuses are present from birth; the frontal sinuses first appear radiologically around 6 yr of age. The ethmoids reach their maximum size relatively early in childhood (7–14 yr of age); the others reach their maximum size after puberty (also see Chapter 365).
3. Lymphoid tissues develop rapidly, reaching adult size by 6 yr of age and continuing to hypertrophy throughout childhood and early adolescence before receding to adult size (Chapter 480).
4. The metabolism of medications and a child's response to them change rapidly in the 1st mo of life and again under hormonal influences in puberty. No single pattern is characteristic of all medications, and individual variation is the rule. Awareness of the possibility of changes and close monitoring are important (see Chapter 711).
5. Nutritional needs as well as a wide variety of biochemical and hematologic values undergo marked developmental changes. For example, the alkaline phosphatase level increases during periods of rapid bone growth (Chapter 691); hemoglobin has a physiologic nadir at approximately 2 mo of age (see Chapter 445).

Chapter 16 - Developmental Assessment

Developmental assessment includes early identification of problems through screening and surveillance, and more definitive assessment including both standardized and nonstandardized measures, as well as integration of information from the developmental, social, and family history and the medical history and examination. The goal of developmental assessment is not only to generate a diagnosis, but equally important to analyze the pattern of strengths and weaknesses in the child, family, and available developmental, educational, and social support systems, in order to direct treatment.

The 1990 Individuals with Disabilities Education Act (IDEA) requires that every state in the United States create a system to identify and treat developmental disabilities in children 3–5 yr of age, and all states extend these entitlements to children beginning at birth to children deemed at risk for developmental problems and to those with established delays. Pediatricians should have a central role in early identification, although in practice this is not always the case (Chapters 29 , 37 , and 39). They are most effective in detecting disabilities associated with congenital or genetic abnormalities. Less dramatic problems in cognition, language, learning, and behavior are often first detected by parents or teachers.

Screening and Surveillance.

The ideal screening test must be highly sensitive (detect nearly all children with problems) and reasonably specific (label few healthy children as ill or delayed). It should also measure what it purports to measure (content validity), give similar results on repeat administration and on administration by different examiners (test-retest and inter-rater reliability), and be relatively quick and inexpensive. Table 16–1 lists several of the more common screening tests and their strengths and limitations. The ideal developmental screening test does not exist.

The most widely used and researched test is the Denver Developmental Screening Test-II (Denver II). However, despite its popularity, it does not function well as a screening test, having limited sensitivity for subtle delays and modest predictive validity. It remains of value because it offers clinicians 125 easily administered developmental test items, with age norms (generated from a large Colorado sample) presented in a convenient one-page format. A series of brief parent questionnaires based on the Denver II milestones and a questionnaire assessing the home environment are also available.

Rapid screening with reasonably good sensitivity and specificity is possible using a structured set of 10 questions eliciting parental concerns in various areas of development. The approach has been formalized as the Parents' Evaluation of Developmental Status (PEDS) questionnaire. The approach works because parents are generally accurate observers of their children's development and behavior. Screening efficiency can be further enhanced by using a formal screening test as a second-level screen for any child “flagged” by systematic parent questioning.

The Ages and Stages Questionnaires (ASQ) are a series of 11 questionnaires designed to be completed at home by parents at several time points from 4 to 48 mo. Validity and reliability are established, with overall agreement with standard developmental tests of 76–91%. However, the ASQ may fail to identify up to 13% of children with developmental delays. Scoring and interpretation are quick, making the ASQ especially suitable for busy practices. The Child Development Inventory is another well-standardized parent-report measure.

Screening for language delays is particularly important because of the strong links between language and cognitive development and later school performance. The Early Language Milestone (ELM) Scale provides pass-fail ratings in expressive, receptive, and visual language, using a format similar to that of the Denver. The scale was normed on a racially mixed sample of middle-class children and has been well validated in both low-and high-risk samples. Administration takes 2–3?min; most items can be completed by parental reporting. Sensitivity for language and cognitive delays is high compared with gold standard diagnostic tests; the test identifies many children even before their parents report being concerned. A modified scoring method can be used to generate a numeric score or age equivalent for diagnostic and research purposes.

Like the ELM, the Clinical Linguistic and Auditory Milestone Scale (CLAMS) is a sequence of language milestones that can be quickly administered, has been validated in infants and toddlers suspected of language delay and in those with known motor delays, and correlates well with standard diagnostic language tests. Paired with a similar series of nonverbal adaptive (problem-solving) milestones, the test correlates well with a gold standard test of mental retardation.

Other procedures that can be useful for developmental screening include the draw-a-person test and the kinetic family drawing (“draw your family, with everybody doing something”). A box of eight new crayons is nearly irresistible to most young children. The crayons can be used for counting, identifying

TABLE 16-1 -- Instruments and Questionnaires for Brief Developmental Assessment

Instrument	Age Range	Time (min)	Notes	Source
Denver-II	0–6 yr	30–45	Better sensitivity for language delays than older version	Denver Developmental Materials, PO Box 6169, Denver, CO 80206

Early Screening Inventory	3–6 yr	15–20	A quick, multidomain screen with good sensitivity and specificity compared with McCarthy Scales (a well-accepted test)	Teachers College Press, 1234 Amsterdam Ave, New York, NY 10027
ELM	0–3 yr	5–10	Well-normed, quick screen for expressive, receptive, and visual language; very useful in infancy; does not assess other domains	Pro-Ed, 8700 Shoal Creek Boulevard, Austin, TX 78757–6897
CAT/CLAMS	0–3 yr	10–20	CLAMS alone gives quick language quotient; CAT/CLAMS correlates well with Bayley (traditional gold standard)	Contact Dr. AJ Capute, The Kennedy Institute for Handicapped Children, 707 North Broadway St., Baltimore, MD 21205
Ages and Stages Questionnaires (ASQ)	4–48 mo	15–20	Series of self-administered questionnaires; multiple domains; good sensitivity and specificity; designed for ages that fall *between* usual pediatric schedule (e.g., 4, 8, 16 months)	Paul H Brookes Publishing Co., PO Box 10624, Baltimore, MD 21285
PEDS	0–8 yr	<5	Well-documented psychometrics; can be self- administered by parents	Ellsworth & Vandermeer Press, 4405 Scenic Drive, Nashville, TN 37204
PEER, PEEX, and PEERAMID	4–15 yr (different tests)	45	Rich source of observations and analysis of school-related functions, weak on validation	Educators Publishing Service, 31 Smith Place, Cambridge, MA 02138–9731, www.epsbooks.com

ELM = Early Language Milestone Scale; CAT = Clinical AdaptiveTest; CLAMS = Clinical Linguistic and Auditory Milestone Scale; PEDS = Parents' Evaluation of Developmental Status; PEER = Pediatric Examination of Educational Readiness; PEEX = Pediatric Early Elementary Examination; PEERAMID = Pediatric Examination of Educational Readiness at Middle Childhood.

Adapted from Blackman JA: Developmental screening: Infants, toddlers, and preschoolers. In Levine MD, Carey WB, Crocker AC (editors): Developmental-Behavioral Pediatrics. Philadelphia, WB Saunders, 1992, pp 617–623.

colors, following simple commands (“Put one crayon in the sink and give two to your mom”) as well as drawing. Much information can be obtained by asking children about their drawings. Asking a child to identify pictures in a children's book or (at older ages) to describe the action in the pictures is a good way to elicit higher-order thinking.

Behavioral and psychiatric problems are common and often accompany developmental concerns. Screening for behavioral problems using the Pediatric Symptom Checklist (Fig. 16–1) is a simple, well-validated method. *Bright Futures: Guidelines for Health Supervision of Infants, Children and Adolescents* features numerous “trigger questions” that function as informal screens for developmental and behavioral adjustment (also see Chapter 5). The companion volume, *Bright Futures in Practice: Mental Health—Volume II: Toolkit*, provides a wealth of other screening instruments and approaches.

LIMITATIONS OF SCREENING.

Screening tests are subject to a number of abuses, including failure to follow the instructions for administration and scoring; overinterpretation of the results (essentially confusing screening with diagnosis); focusing on the screening test to the exclusion of other sources of information; screening too infrequently; using tests that are culturally biased; and failing to follow up with further assessments and treatment when indicated. Community-wide programs of early developmental screening, while of intuitive value, have not been shown to actually improve developmental outcomes at school age. Screening and assessment without effective follow-up may do more harm than good.

DEVELOPMENTAL SURVEILLANCE.

Surveillance has been put forward as an antidote to the shortcomings of developmental screening. The transactional nature of development ensures that a child's status at any single point in time can never entirely predict later development. As with physical growth, a series of observations made over time provides much more information than an assessment at a single time point, allowing for estimation of developmental rate. Prediction is more accurate when it makes use of several sources of information, including the medical and social histories. These considerations underlie the concept of developmental surveillance, a process that includes regular elicitation of the developmental history, attention to parental concerns, careful developmental observations, and promotion of development.

Critics of surveillance have pointed out that a pediatrician's judgment is subject to a host of biases that undermine its accuracy. Pediatricians may overestimate IQ in children they know well or in children who are physically attractive or socially adept.

An approach combining ongoing surveillance with periodic use of screening tests may be the most effective and practical solution. A multidomain battery of milestones, such as the Denver, as well as systematically applied informal observations can be used as a framework for regular observations rather than as a stand-alone test. Parent questionnaires can streamline data collection and may encourage parents to voice their questions and concerns. Early identification of developmental and emotional problems will be maximized by keeping the following five principles in mind:

1. Parents, as a rule, are accurate observers of their children's behaviors; parental concerns about possible developmental delays are often appropriate and need to be taken seriously; conversely, a lack of parental concern should not be relied on as the sole indicator of normal development.
2. No child is too young for formal audiologic testing. In-office audiologic screening cannot rule out clinically significant hearing loss. Hearing-impaired children often use visual cues to “pass” hearing tests. Audiologic testing is indicated by the presence of any of the historic and physical findings listed in Box 16–1 .
3. Risk factors are additive. Biologic impairments that may be relatively minor on their own (e.g., recurrent otitis) may have major impacts in the presence of environmental risk factors (e.g., maternal depression). Awareness of problems in one area should trigger increased vigilance in other areas. For example, emotional problems are common causes and consequences of cognitive and language disorders; environmental risk factors, such as maternal depression, frequently coexist with biologic risks, such as prematurity or lead toxicity.
4. Discomfort, fatigue, shyness, and oppositionality may adversely affect a child's performance on developmental

testing. Rescreening is appropriate when these factors are suspected but should not be unduly delayed. Caution should be exercised before proclaiming that a child will “grow out of” a problem.
5. Pediatricians and parents may worry about the adverse effects of labeling a child. Screening test results are not diagnoses. Follow-up assessment and intervention are critical. It is a child's progress over time that is important rather than any labels given along the way. In all but the most severe cases, a child's progress cannot be accurately predicted at the outset; an attitude of realistic optimism is appropriate.

Figure 16-1 The Pediatric Symptom Checklist. (From Little M, Murphy JM, Jellinek MS, et al: Screening 4- and 5-year-old children for psychosocial dysfunction: A preliminary study with the pediatric symptom checklist. *J Dev Behav Pediatr* 1994;15:191.)

DIAGNOSTIC ASSESSMENT

Once a child has been identified as having a potential problem, the next step is diagnostic assessment. The form and content of the assessment depend on the age of the child, the nature of the problem, and the available medical and community resources. Pediatricians function as part of a team that may also include psychologists, educators, social workers, and other professionals. Central to a pediatrician's role is medical evaluation of a developmentally disabled child (also see Chapter 37).

Medical Evaluation of Developmental Delays.

The prevalence of more common developmental disabilities is listed in Table 16–2 . The medical evaluation includes history, physical examination, and laboratory testing. Taking a thorough family history, including neurologic, psychiatric, and social difficulties (e.g., legal problems), is indispensable. The family history may shed light on the multigenerational origins of family dysfunction and resilience and may illuminate the parents' beliefs about the causes of the child's problem (e.g., “He's just like his uncle”) (see Chapter 17).

The prenatal history should include a search for potential teratogenic exposures, including radiation or medications, infectious illnesses, fever, addictive substances, and trauma. The perinatal history includes birthweight, gestational age, Apgar scores, and any medical complications (Chapter 83.1). Postnatal medical factors that are sometimes overlooked include chronic respiratory or allergic illness, recurrent otitis, head trauma, and sleep problems (particularly signs of obstructive sleep apnea [Chapter 369]).

In the physical examination, points of particular importance include growth parameters and head circumference, facial and other dysmorphology, eye findings (e.g., cataracts in various inborn errors of metabolism), and signs of neurocutaneous disorders (café-au-lait spots in neurofibromatosis, hypopigmented macules in tuberous sclerosis).

No single set of laboratory tests is indicated in all cases. Most states screen for phenylketonuria, hypothyroidism, and other metabolic conditions in the neonatal period. Iron deficiency and lead toxicity are common contributors to developmental delays and are easily detected. Electroencephalograms and neuroimaging are not routinely indicated but should be used if there is clinical suspicion of seizure or encephalopathy or in cases of microcephaly or of rapidly expanding head circumference.

The medical evaluation for mental retardation (Chapter 37.2) and autism (Chapter 27.1) should include chromosomal and molecular biologic testing for fragile X, the most commonly

identified genetic cause of mental retardation (Chapter 70). Classic physical findings in fragile X such as long faces, large ears, and large testes may be absent in infancy. Milder forms of cognitive and behavioral disturbance have been associated with partial mutations and heterozygosity for fragile X in girls as well as boys. A diagnosis of fragile X does not change therapy but has implications for genetic counseling. Ammonia and organic and amino acids may be included to screen for metabolic disease. With progressive loss of milestones, and particularly if there is associated growth delay, human immunodeficiency virus must be considered (Chapter 254).

Developmental Diagnosis for Infants and Preschool-Aged Children.

The most widely used newborn behavioral examination is the Brazelton Neonatal Behavioral Assessment Scale (NBAS). The NBAS allows quantitative estimation of an infant's neurologic intactness, adaptation to extrauterine life, primitive reflexes, state organization, self-regulatory ability, and interactive capacities from birth to 1 mo. The examination takes approximately 30–45?min and requires extensive training for an examiner to reach proficiency.

The NBAS is a poor predictor of later development, not surprising given the salience of environmental influences on development. In practice, the assessment functions well as an intervention in its own right (Chapter 9). Demonstrating neonates' behavioral abilities and vulnerabilities to their parents (e.g., their ability to track visually and turn toward sounds and their vulnerability to overstimulation) is consistently associated with improvements in the child-rearing environment months later.

For older infants and preschool-aged children, the diagnostic process may include formal developmental testing, playroom observations, parent and family interviews, home observations, and team meetings. It often involves a multidisciplinary team of educators, psychologists, parents, social workers, therapists, and pediatricians. Pediatricians contribute medical expertise and knowledge of the child and family accumulated over time. Diagnostic and therapeutic services are provided through the federal- and state-mandated early intervention programs and through multidisciplinary child development teams.

For young children, intervention relies on parental participation. The federal Early Intervention law (PL 105-17) mandates family involvement at all stages of the process of assessment, construction of a service plan, and monitoring of a child's progress. Pediatricians can help parents understand their rights and responsibilities under the law, review the process of developmental assessment and service planning to ensure that the parents are comfortable with the plan, and advocate with the early intervention system on behalf of a child.

To monitor a child's progress and advise the parents, a pediatrician needs to have realistic expectations about the effectiveness of early intervention. For children who face predominantly social/environmental risk factors (e.g., poverty), strong evidence shows that early intervention can raise IQ in the

TABLE 16-2 -- **Prevalence of Developmental Disabilities**

Condition	Prevalence per 1,000

short term, as well as rates of school completion, job satisfaction, and social adjustment in the long term. For children at biologic risk because of prematurity, interventions combining direct therapy for a child with family support (home visiting, parent education) have resulted in significant gains in cognitive and emotional development. For children with established disabilities, the findings are more complex and controversial. Gains in IQ are modest overall, with greater gains among less severely affected children. However, improvements in family adjustment and alleviation of parental stress are consistently found. For children with autism-spectrum disorders, intensive language and interpersonal therapy may result in significant gains.

Diagnostic Assessment for School-Aged Children.

Pediatricians are often called on to diagnose specific learning disabilities or attention deficit disorder in school-aged children with academic or behavioral problems or both (Chapter 29). The medical evaluation includes the factors discussed in the prior chapters. Vision and hearing deficits, although seldom the sole causes of school problems, must be evaluated. The interview should assess functioning in the home, the school, and the neighborhood and with peers (Chapters 13 and 14).

Definitive diagnosis usually requires a team effort. Educational testing is indicated to define areas of academic strength and weakness. Psychologic evaluation is indicated to assess emotional problems, such as depression or anxiety, that may be either causes or consequences of the school problems. Assessment of family functioning is essential. Neuropsychologic testing may be indicated to assess specific functional deficits (short-term memory, verbal processing) that may cause a child to be inattentive (Chapters 13 and 29). Pediatricians can facilitate these referrals and synthesize the information for parents and the school. Pediatricians with special interest in assessment of learning problems may also choose to use one of a series of neurodevelopmental tests, such as the Pediatric Early Elementary Examination (PEEX), to obtain a better sense of a child's functioning in various school-related cognitive areas (see Table 16–1).

Referrals to psychologic and educational specialists may be expensive and may not be covered by insurance. An alternative is assessment in the school. In the United States, under federal law, each child is entitled to comprehensive educational assessment and the establishment of an individualized educational plan (IEP) as part of free public education. The assessment must be completed within approximately 2–3 mo, and parents must approve the IEP before it can be instituted.

In practice, the quality of these educational assessments varies depending on the skills of the school psychologist, the workload, and the educational resources available within the school system. If the assessment is inadequate, the parents have the right to demand an independent evaluation at the school's expense. The following questions can aid pediatricians in the important task of assessing the assessment:

1. Was sufficient time taken for the child to feel comfortable with the examiner and setting? The anxiety of confronting a stranger in a strange room may lower a child's score considerably.
2. Were a psychologic interview and projective testing as well as the more standard educational tests performed? Some school psychologists ignore the emotional aspects of learning, focusing solely on the cognitive.
3. Was IQ testing done? Were individual or group tests done?
4. Did the testing address all major areas of functioning (e.g., receptive and expressive language, visuomotor skills, short- and long-term memory)?
5. Was an attempt made to synthesize the findings in the report, or were the scores simply reported?

Part 3 - Psychologic Disorders

Chapter 17 - Assessment and Interviewing

17.1 The Clinical Interview (History)

Neil W. Boris
Marc A. Forman
Jorge H. Daruna

The clinical interview is a major means of engaging patients and their families in active management of their own care (see Chapters 5 and 6). Primary care practitioners must manage both the physical and behavioral health of children. The clinical interview must, therefore, serve as both a tool for gathering information and a means for influencing behavior. One well-practiced part of a clinical interview in most pediatric and general medical settings is the simple collection of medical data related to the signs and symptoms of a presenting illness, the nature and course of past medical illnesses, the family history, and a review of systems. Other aspects of a patient's life, such as psychosocial functioning, often get less or scant attention in interviewing. However, the presence of psychosocial problems can significantly influence the course of a disease, alter compliance with treatment recommendations, or even be the source of a patient or family's “hidden agenda” related to a given visit. Furthermore, managing behavioral concerns without understanding family functioning or the child's emotional state is akin to driving while blind. Pediatricians need to use clinical interviews to assess the emotional states of their patients and uncover clues that might point to psychosocial distress or disturbance within the family context. Understanding developmental issues related to information gathering and principles of family assessment is also central to successful interviewing (see also Chapter 6).

Assessing a child's emotional state or delving into family functioning requires both specific skills and a considered approach consistent with the individual physician's style. The first goal is to build rapport with both family and child. Pediatricians who develop modes of interaction matched to the child's developmental stage will likely

have the most success building rapport, and a brief review of developmental issues related to engaging patients and their families follows. However, there are some general principles regarding interviewing and assessment that are useful to consider first.

Efficient communication requires unbroken attention; a closed door and no interruptions promote efficiency. Ensuring privacy, whenever possible, will increase the yield of information generally, and is especially important when psychosocial issues are being discussed. Privacy is not always easily attained (e.g., an open ward) and without it the physician may not be aware that their patient (or the family) has not felt comfortable enough to share relevant information. Setting aside adequate time for an interview is also important. Comprehensively exploring both psychosocial and biomedical aspects of the condition of a child who has just become a new patient needs at least 30–40?min for significant exchange of the most basic relevant information.

The use of time is equally important. Building rapport with parents requires taking time to address their major concerns at each visit. The pediatrician should follow the opening attempt to build rapport with the child by asking open-ended questions to the caregivers about their concerns or questions. Using patient-centered interviewing improves data gathering and increases patient satisfaction, which, in turn, improves compliance. Patient-centered interviewing refers to guiding the patient or parents through the interview by explicitly allowing them to present their foremost concerns. With practice, it takes no longer to focus on the concerns of patient and/or parent, than to “lead” the interview. Centering the dialogue on the patient or family's agenda often results in less time required to undo misunderstandings later. Furthermore, it is typically possible to multi-task, by, for instance, following up on a parent's questions or concerns while finishing the physical examination of the child. Finally, a primary determinant of malpractice claims is poor physician-patient (or family) communication, and, from the patient's perspective, “not being heard” is the central communication problem.

A great deal of interview data can be gathered through careful attention to nonverbal cues. Just as the physician who palpates but does not auscultate may miss important data on a physical examination, the physician who does not actively note information about facial expressions or body language will miss important information related to the patient's mental state. For example, an adolescent who is expressionless and averts his or her eyes is obviously uncomfortable. Unless the physician notes this and inquires gently about what might be bothering the patient, an opportunity to reach that adolescent will be missed. Furthermore, the patient with unmet needs may return or seek care elsewhere, effectively decreasing efficiency. Scanning for nonverbal cues and commenting on them is part of effective interviewing.

Often, the goals of patient encounters go beyond building rapport with the child, incorporating the concerns of the family into the interview, and gathering nonverbal data. Typically, there is some information that the physician must communicate. Again, presenting information should involve more than words. For instance, simply using eye contact and a positive tone of voice when detailing a medication regimen will increase the likelihood that the patient or parent will understand the information. Legible written instructions and a noncondescending explanation of why the patient should comply will further increase compliance. Finally, when necessary, offering a reminder call may prove effective. It may be necessary to provide positive, clear directions repeatedly.

One of the challenges of working with children is that effective interaction requires attention to developmental issues. What works for a child at one developmental stage will not work at another stage. What follows are some considerations and guidelines for interviewing matched to developmental stages.

Infancy and Early Childhood.

Infants and toddlers have tremendous capacity for forming memories, though they do not have language

---

available to describe them. This means that the frequent office or clinic visits before 3 yr of age can collectively provide a “positive memory bank” for an individual child, which can then become the building blocks for a positive and meaningful relationship with the child and his or her family. The practitioner who actively makes eye contact with and plays, even briefly, with young children will create these positive relationship building blocks. Furthermore, paying this kind of direct attention to the young child is almost always comforting to parents.

Initial or casual encounters with preschool children are often made easier when introduced in a whisper, which young children may find more personal, private, and reassuring than jollity; they commonly whisper in response. When children are old enough, at 4–5 yr, it is important for the pediatrician to form the habit of discussing with them their symptoms, diagnoses, and treatments in terms they can understand. The use of drawings to illustrate and explain medical problems can be very useful.

Caring for an infant is challenging to most parents. Using a prenatal visit to understand a family's expectations, ways of coping, and level of stress is time well spent. Predicting for new parents what are the common stress points and setting basic ground rules for when and how to call for help will typically decrease calls to the office. Providing web-based or written parent resources is often helpful. Maternal depression has a significant impact on the infant and young child. Infants of depressed mothers have been found to have alterations of in utero physiologic responsiveness and in electroencephalography in the first weeks of life compared with matched controls. Furthermore, inadequate maternal responsiveness to their infants is correlated with the degree of maternal depression and, in time, with insecure child attachment. One or two questions about mood and functioning are, therefore, necessary at the first postnatal visit (“Some parents find the weeks after birth very stressful—how are you doing?” “Have you had periods of sadness or depression since your baby was born?”). Often, depressed mood is evident through nonverbal communication. If the parent admits to significant sadness or just appears sad and overwhelmed, having a depression screening instrument in the office (such as the Beck Depression Inventory) will assist greatly in deciding which parents need referral. The vast majority of parents are relieved to be able to share their difficulties and will readily fill out a screening questionnaire. The pediatrician who recognizes maternal depression and completes a referral may significantly decrease the

untoward impact of this depression on their patient.

The School-Aged Child.

As children reach school age, asking about their interests directly at the outset of any interaction in developmentally appropriate language is of paramount importance. Noting specific interests or comments in the patient record will allow for follow-up queries at subsequent visits and communicate the physician's attentiveness and caring. School-aged children are largely well, but family or peer-relationship problems and worries or fears are extremely common and should be inquired about. These concerns, when accompanied by learning difficulties, attention or behavioral problems, anxiety, or other like symptoms, may together be very stressful for children and their families. The clinician should ask how everyone gets along at home and which children the child likes to spend time with. Children who do not have a best friend (or friends) or who express concerns about parental fighting may, for instance, require extra support or even referral for counseling. This is especially true if they are performing poorly at school or if the parent reports behavior problems. When this is the case, getting the parent(s) and at least one teacher to fill out a behavioral problems screening instrument (such as the Child Behavior Checklist) may be helpful for identifying and tracking specific problems. Behavioral screening instruments, however, are inadequate for making psychiatric diagnoses.

Parents of school-aged children may be stressed. The pediatrician who inquires about parental concerns and asks open-ended questions about the child's social functioning will allow for useful discussion of stressors. Of particular importance, at all stages of development, is domestic violence (see Chapters 5 and 34). Domestic violence is both common and a source of shame for parents; active questioning of parents is required to uncover it. Furthermore, for the school-aged child, domestic violence is both frightening and confusing—children are unlikely to be able to put their feelings into words spontaneously. Domestic violence is both greatly under-recognized and associated with serious family morbidity and mortality. Many practitioners feel anxious inquiring about domestic violence, but making a query about family discourse need not be off-putting to the family. For instance, first stating: “At this visit, I usually ask about how a child's parents are handling their stress—how are you doing in this regard?” suggests that family concerns are also the concern of the pediatrician. A follow-up question might be: “You know, one issue that really impacts children is parental fighting, especially physical fights—has this ever been a problem in your home?” Avoiding accusation puts parents at ease, and data suggest that, when asked, both victims and victimizers will speak about the issue. However, it is true that parents are sometimes more comfortable talking about these issues outside the child's presence and the pediatrician should offer this option. Unfortunately, there are no simple demographic indicators of families at greatest risk for violence at home: The problem is common for single parents but cuts across social strata. When the pediatrician hears about physical fighting in the home, he or she should ask about the current situation and assess family safety directly. A referral to a shelter for ongoing violence is of paramount importance, though many families will need assistance in following through with this recommendation. At a minimum, both giving shelter numbers and scheduling another appointment with the pediatrician within 2 wk are necessary. Having the parent fill out a behavioral problems screening checklist is also indicated for every domestic violence situation; the impact of this stressor on the child is clearly important and should be documented. Referral may be necessary particularly when aggression, withdrawal, school failure, or role reversal (e.g., the child becomes the parent's caretaker) are evident.

Adolescents.

A key developmental milestone for each adolescent is gaining autonomy from his or her parents or caretakers (see Chapter 14 and Part XII). The pediatrician can support the adolescent in gaining autonomy by directing the interview to the adolescent, beginning at the time of puberty. By inviting the parents to leave the room, the physician affords the adolescent a sense of privacy and increases the chance of gaining insight into issues that would not be discussed in front of parents. Confidentiality is important to consider when interviewing adolescents. Though adolescents highly value private consultation with their physicians, a survey of primary care providers revealed that a minority of practitioners ask parents to leave the room during health visits. Physical examinations of adolescents should also be conducted with their parents not present, unless a patient requests otherwise.

Although adolescence has been traditionally viewed as a period of “storm and stress,” there is evidence that most adolescents do not experience more stress at this developmental stage than at others. On the other hand, risk-taking behavior is not uncommon among adolescents and most adolescents report peer pressure to take risks. Experimentation with alcohol, tobacco, drugs, and sex are typical. Adolescence is also a period when the incidences of several major mental illnesses increase dramatically. Major depression, bipolar disorder, panic disorder, and schizophrenia are chronic conditions, and there is evidence that early stabilization of these illnesses in adolescents may improve long-term outcome. Finally, adolescence is a stage during

which consolidation of sexual orientation generally occurs and this process, especially for many of the youth who self-identify as homosexual, is associated with considerable stress, elevated levels of risk-taking, and higher rates of suicide attempts.

Each adolescent visit requires a careful social history and an opportunity for discussion about how to make choices regarding tobacco use, alcohol use, drug use, and sexual risk-taking. Familiarity with a good psychiatric review of symptoms is necessary for cases in which mental illness is suspected. The adolescent interview requires careful attention to detail, and using a structured format for briefly assessing risk-taking behaviors, social stressors, sexual identity and orientation, and psychologic adjustment is recommended. Suicidal ideation should also be discussed. During adolescence more lives will be saved by a good interview and respectful counseling about behavior than by a thorough physical examination. Inquiring about suicide does not promote suicidal ideation.

With practice, an interview that begins with open-ended questions about social functioning and finishes with an inquiry about suicidal ideation should be possible in a 15-min visit with an adolescent. Good eye contact, a practiced transition statement (e.g., “now I'd like to ask about some issues that I ask all teens about”), and the use

of reflection and encouragement will put most adolescents at ease. Even if the pediatrician gets a negative response to questions about suicidal ideation, he or she will have certified that a topic as “personal” as suicide is one that the adolescent can return to talk about. Creating an atmosphere in which the adolescent has “permission” to discuss his or her most private concerns is critical; when the pediatrician takes the lead in opening up topics such as drug use and sexual practices, “permission” is granted.

For the parent, caring for an adolescent can be exasperating. Open communication between parents and their teenage children promotes positive adjustment for the adolescent. However, parents often feel disconnected from their adolescents, in part because peer influence becomes more and more important during adolescence, resulting in a degree of withdrawal from parents. The pediatrician can play the role of “parenting coach” quite effectively at this developmental stage by both modeling (e.g., asking to meet with the adolescent alone to talk about teen issues) and suggesting that the parent routinely do the same. Again, addressing parents' specific concerns is important, and there are a number of web-based and print resources that can provide “backup” for the busy physician; parents typically will value being pointed in the direction of good parenting books and resources.

OTHER SOURCES FOR ASSESSMENT

Institutions or Agencies.

School reports are important to the psychosocial assessment, especially if they include both an academic evaluation and a description of the child's relationships with schoolmates and teachers. Requests for school reports should be made only with the written permission of the child's parents or legal guardians. Reports from child-care agencies may also be helpful, especially in the case of adopted children or children in foster care. Such agencies often have extensive background material and may have reports of earlier psychologic examinations.

Psychologic Testing.

A number of instruments may be administered to parents by trained pediatric staff to assess development, behavioral problems, family stress, and parenting skills. It is wise to have a set of instruments and their scoring templates and age norms at the office. Some examples of particularly helpful instruments include the Vineland Adaptive Behavior Scales, the Child Behavior Checklist, the Infant-Toddler Social-Emotional Assessment, the Childhood Depression Inventory, and the Parenting Stress Index. Use of these validated checklists can facilitate early identification of problems that may necessitate referral to a child psychiatrist or other appropriate specialist. Although checklists do not provide diagnoses, they will assist in improving assessment efficiency, tracking symptoms, and deciding whom to refer.

Individual psychologic testing should be conducted by trained psychologists. Comprehensive assessments of sensory-motor development, language, and academic achievement may require additional involvement of occupational therapists, speech/language pathologists, or educational consultants. The major tests used in the psychologic assessment of children can be classified into four groups: (1) tests of general intelligence; (2) tests of academic achievement; (3) tests of specific sensory, motor, or cognitive functions; and (4) tests of behavioral or personality characteristics. Tests that are widely used to assess general cognitive proficiency or intelligence for specific age groups (shown in parentheses) include the following: The Bayley Scales of Infant Development (0–42 mo); Stanford-Binet Intelligence Scale, 4th edition (2 yr–adult); McCarthy Scales of Children's Abilities (2.5–8.5 yr); Kaufman Assessment Battery for Children (2.5–12.5 yr); Wechsler Preschool and Primary Intelligence Scale-Revised (3–7 yr); Wechsler Intelligence Scale for Children, 3rd edition (6–16 yr); and Wechsler Adult Intelligence Scale, 3rd edition (16 yr– adult).

Academic achievement tests are designed to measure competence in specific areas of knowledge or skill (e.g., arithmetic, reading) usually acquired through formal education in schools. Some frequently used tests in this category include the Peabody Individual Achievement Test, Revised; the Wide Range Achievement Test, 3rd edition; and the Woodcock-Johnson Psychoeducational Battery, Revised.

Numerous tests have been developed to measure more circumscribed skills such as auditory perception (e.g., Seashore Rhythms test); language (e.g., Boston Naming Test); verbal memory (e.g., California Verbal Learning Test); abstract reasoning (e.g., Children's Category Test; Wisconsin Card Sorting Test); constructional ability and nonverbal memory (e.g., Rey's Complex Figure test); motor proficiency (e.g., Finger Tapping Test; Purdue Pegboard Test); and sustained attention (e.g., Continuous Performance tests).

Evaluation of behavioral or personality characteristics often relies on questionnaires completed by parents or teachers (e.g., Conners Rating Scales; Child Behavior Checklist) to rate the frequency with which children show various behaviors (e.g., hyperactivity, aggression). In older children and adolescents, it is also possible to assess self-reported feelings and thoughts using questionnaires such as the Youth Self-Report, Piers-Harris Self-Concept Scale, or Reynolds Child Depression Scale. These scales are useful but do not substitute for carefully conducted clinical interviews. Assessments using projective tests, which require a child to report associations provoked by relatively abstract pictures (e.g., Rorschach inkblot test) or make up stories to pictures depicting specific situations (e.g., Children's Apperception Test; Thematic Apperception Test) are useful in uncovering issues or concerns that preoccupy children as well as distortions or idiosyncrasies that characterize their thought processes.

Neuropsychologic testing is synonymous with extensive testing using various instruments from all of the categories listed earlier. However, it should be noted that more testing is not necessarily helpful. Tests should be chosen to address specific questions that will help make decisions about interventions. In choosing tests, it is essential that they have demonstrable reliability and validity. They should also have norms that are relatively recent and representative of the general population. An ongoing collaborative relationship with a psychologist or other specialist facilitates appropriate use of testing in a pediatric practice.

Psychologic tests should not be used to differentiate between so-called organic and functional causes of behavior. All causes of

behavior are organic in the sense that behavior is biologically driven. If a question arises about the type of biologic disturbance that may underlie a behavioral impairment, other forms of assessment should be used, such as brain imaging techniques; neurophysiologic, endocrinologic, and immunologic tests; and/ or chromosomal-genetic studies.

Psychiatric Consultation.

A psychiatric consultation may be a valuable part of assessment of child symptoms (even “physical” symptoms) or family stress or discord. Physicians should inform both parent and child what the psychiatric consultation is intended to assess. The child's consent is helpful and is usually easily obtained when the reasons for referral are explained and some idea of what to expect is furnished. Helpful information on psychiatric assessment is available to both the physician and parents. In fact, standardized guidelines for psychiatric assessment of infants, children, and adolescents have been published by the American Academy of Child and Adolescent Psychiatry, and free “Facts for Families” sheets on various psychiatric symptoms are available on the web or by phone. The need for a psychiatric consultation or referral can perhaps best be expressed in terms of the joint need of the family and physician for help in areas where the psychiatrist has special expertise, with the understanding that the collaboration of physician and family in management of the other health care needs of the child will remain intact.

Correlation of Data.

Physicians must avoid early diagnostic closure even when parents' initial description of their problem gives a reasonably clear idea of what is going on. So long as physicians remain receptive and perceptive listeners, new and important information will emerge, as parents and perhaps patients begin to feel more trusting and as they are educated by a physician's questions. Furthermore, weighing of data must be done in the context of a family's sociocultural pattern (see Chapter 3). It is important that physicians not use their personal value system or style of living as a yardstick against which to measure a family's behavior or their success or failure in coping with their life situation. A family's feelings of anger, frustration, anxiety, failure, or depression are more valid indicators of where they need help.

It is also important that the principal item of concern be accurately identified. Parents may present as the prime concern, for example, a problem such as bed-wetting of many years' duration. Why then have they come for help now? It is important to determine whether there may be important hidden issues the parents do not recognize or acknowledge or cannot face. By the same token, it must be understood that the parents' assessment of the problem is critical for the child. Physicians, having collected and assessed appropriate data, sometimes can only conclude that children presented by their parents as having a problem are functioning within normal limits. In such a case, it must be determined what personal, familial, social, or cultural considerations compel the parents to see their child's behavior as a major problem. It must then be determined what re-education they may need to feel reassured and not be left with the impression that their anxiety has been casually dismissed.

Referral.

When problems have not been internalized by the child, it may be sufficient simply to counsel the parents, school personnel, or both. If this has been done and a maladaptive child or situation continues to present problems, the child and family will probably require more intensive or extensive help and should be referred to a child psychiatrist or psychiatric clinic. It is important that pediatricians avoid communicating that psychiatric referral is a last resort. The need for psychiatric consultation or referral should be expressed in terms of the joint need of the family and physician for help in areas where the psychiatrist has special expertise, with the understanding that the collaboration of physician and family in management of the other health care needs of the child remains intact.

17.2 Psychosocial Problems

Richard Dalton
Marc A. Forman

A psychosocial disorder in a child may be manifested as a disturbance in feelings (e.g., depression, anxiety), in bodily functions (e.g., psychosomatic disorders), in behavior (e.g., conduct disturbances, passive-aggressive behavior), or in performance (e.g., learning problems). Dysfunction may involve any or all of these areas. Psychosocial problems may be produced by such physical or emotional stresses as birth defects, physical injury, inconsistent and contradictory child-rearing practices, marital conflict, child abuse and neglect, overindulgence, chronic illness, and so on. In general, particular agents do not produce specific symptoms or disorders; rather, children's psychosocial problems are multifactorial in origin, their expression depending on many variables, including temperament, developmental level, the nature and duration of stress, past experiences, and the coping and adaptive abilities of the family. Chronic stresses or a series of stressful events is much more difficult for a child and family to manage than a single acute stressful episode. Children may react immediately to traumatic events or may keep their feelings dormant until maladaptive reactions become apparent during later periods of vulnerability.

Anticipatory guidance during periods of stress may considerably help children and their families to achieve more positive outcomes. Parents should be encouraged to prepare their children in advance for potentially traumatic events that can be anticipated (e.g., elective surgery, separation, or divorce). Children should be allowed or encouraged to express their feelings of dismay, fear, or anger rather than being told to be a "good girl" or "brave boy."

Infants and toddlers tend to react to stressful situations with impairment of physiologic functions, such as disturbances of feeding and sleep, with relatively global expressions of anger or fear, as in temper tantrums, or with withdrawal and avoidance behavior. School-aged children demonstrate their difficulties through altered interpersonal relationships with peers and family members, through impairment of school performance, by the development of specific psychologic syndromes, such as psychosomatic disorders, or by regressing to earlier, more childish modes of functioning.

Parents are frequently concerned whether the particular behaviors of their children are normal or whether they represent problems that require intervention. Some "symptomatic" actions of children may be part of normal development. For example, a temper tantrum may express the normal negativism of a toddler; on the other hand, temper tantrums on slight provocation in a 6-yr-old child may indicate psychosocial disturbance. Whether behavior is judged to be a developmental variation or evidence of a more serious problem depends on the age

of the child; on the frequency, intensity, and number of symptoms; and especially on the degree of functional impairment. The decision of parents to seek help is determined, in turn, by the characteristics of their children's behavior; by the amount of distress it causes the children, parents, teachers, and others; and by their past experiences in discussing psychosocial matters with their physicians. **REFERENCES**

Chapter 18 - Psychiatric Considerations of Central Nervous System Injury

Jorge H. Daruna
Marc A. Forman
Neil W. Boris

Injury to the central nervous system (CNS) as a result of physical trauma, exposure to toxic substances, or infection may cause psychiatric disturbances.

Epidemiology.

Head injury is a relatively common event in pediatric populations. Infants and young children may be victims of abuse (see Chapter 35). Children of all ages may be injured in falls or automobile accidents (see Chapter 50). Older children and adolescents may be further affected by sports-related head trauma (see Chapter 677). Severity of injury has been found to predict behavioral disturbance. Although severity can be difficult to gauge in some instances, loss of consciousness exceeding 20–30?min is often associated with serious sequelae.

Injuries early in life may be more generally incapacitating than those that occur later, even though neural plasticity remains high in young children. The immature brain may be more globally affected, even though deficits may not be immediately evident and only gradually manifest as the child develops behaviorally. Brain injury before the age of 3 yr has been associated with later seizures, which independently increase the risk of behavioral disturbance. Early brain injury can also result from inadvertent ingestion of neurotoxic substances such as lead, which causes significant behavioral morbidity (Chapter 703).

Estimates of the frequency of behavioral disturbance after brain injury are variable, but consistently indicate that there is an increased risk of psychiatric disorder. In the case of severe brain injury, the estimates of psychiatric morbidity range from 54% to 76%, though there is great variability in both severity and course of postinjury disturbance.

Clinical Manifestations.

Most often the behavioral disturbance resembles attention-deficit/hyperactivity

disorder (ADHD) or takes the form of a depressive disorder. Psychosis is not generally seen as a result of brain injury in childhood. Typically, there may be problems with motor function. Cognitive skills, particularly attention and memory, may be compromised. Impairments in the regulation of emotion and social behavior occur frequently. Affected children can seem to lack insight and empathy. Some deficits may not be apparent until late childhood or adolescence, when there is a need for greater efficiency, flexibility, and speed in cognitive processing. Those with the highest risk for significant behavioral disturbance come predominantly from the groups who incurred severe injury, who had prior behavioral problems, and whose family functions poorly. The serious head trauma either gives rise to novel psychiatric disorders or further aggravates a psychiatric disorder that may have arisen originally as a result of genetic and/or psychosocial influences. Even when the head injury has been judged to be mild, there may be educational problems in as many as 25–50% of afflicted children.

Insults to the brain can occur prenatally and have lifelong consequences. Preterm birth may adversely impact the development of neural systems. Very premature infants are at increased risk for severe neurodevelopmental disorders and exhibit cognitive deficits, educational handicaps, and behavioral disturbances, particularly ADHD and anxiety disorders. Another major cause of prenatal brain injury is exposure to toxic substances such as tobacco, alcohol, and a variety of medicines, including illicit drugs. Prenatal exposure to such substances is associated with impairment in growth, cognition, and self-regulation of behavior. However, the initial impression that crack-cocaine is especially devastating has not been supported by research that controls for confounding variables such as harsh psychosocial conditions and use of legal drugs like tobacco and alcohol, although one study reports that cocaine-exposed infants show significant cognitive deficits by 2 yr, even when the previously noted variables are controlled.

Infections during pregnancy also can cause serious behavioral morbidity. In some cases, the behavioral disturbance is not evident until late adolescence. For example, there is evidence that at least some cases of schizophrenia may be attributable to maternal viral infection during pregnancy. Postnatal infections of the CNS, such as encephalitis, also may cause brain injury, with behavioral consequences that resemble the range of disorders seen after physical or toxic trauma to the brain. Behavioral disturbances may also follow infection with organisms such as group A ß-hemolytic streptococci as the result of antibodies to the pathogen that may cross react with neural tissue. In particular, obsessive-compulsive disorder and Tourette disorder have been reported to result from such an autoimmune process (see Chapter 21).

Treatment.

The most significant factor in a child's adjustment to brain injury is the capacity of the family to cope and adapt. This in turn can be facilitated by access to professional expertise, as well as to educational programs and other resources available in the community. Initially, it is probably best to not give premature reassurance, particularly because what may seem to be minimal early deficits may later manifest as impairments of greater significance. Such children need to be followed and periodically evaluated as they mature. Most children who develop psychiatric disturbances as a result of CNS injury, as well as their families, need appropriate psychosocial support and educational

programs designed to remediate specific disorders. A frequently beneficial approach is to assist the child to understand his or her maladaptive behavioral patterns and focus on developing strategies for adequate self-regulation and skill acquisition; coaching and practice are very important. It is also important for the child to have the opportunity to discuss troubling feelings and thoughts that may be provoked by the actions of others who may reject or tease the child.

The parents and other family members have their own concerns and will need guidance and emotional support to deal effectively with the child's behavior both at home and at school. Fair and firm discipline is always useful. Behavior modification techniques can help the child to acquire situation-appropriate behaviors.

Pharmacologic treatments may be helpful as well. Stimulant medications can improve attention, decrease overactivity, and thus improve behavior at school. Affective symptoms may be treated with antidepressants and mood stabilizers. Severe impulsivity and agitation may respond to low doses of atypical neuroleptics. Given the increased risk of seizure in brain-injured children, medicines that lower the seizure threshold should be avoided. It should also be kept in mind that brain-injured children are a heterogeneous group for whom the efficacy of specific pharmacologic agents has not been sufficiently investigated.

Chapter 19 - Psychosomatic Illness

Alessandra N. Kazura
Neil W. Boris
Richard Dalton

Physiologic regulation is influenced by psychologic state in humans; most organ systems and many medical conditions are stress sensitive. From the bronchial constriction of asthma to the weal and flare skin response, there are many examples of chronic or recurring conditions whose physiologic course is related to psychologic adjustment. The *Diagnostic and Statistical Manual* (DSM) nosology distinguishes three broad categories of psychosomatic disorders:

1. Psychophysiologic disorders occur when psychologic conflict affects the development or recurrence of a physical condition (e.g., asthma, eczema, or irritable bowel syndrome). Though physical symptoms are observable, the course of these disorders is influenced by psychologic function.
2. Somatoform disorders present with somatic complaints and/or dysfunctions that are not under conscious control and for which physical findings are absent or insufficient to explain all complaints. These disorders include body dysmorphic disorder, conversion disorder, hypochondriasis, somatization disorder, and somatoform pain disorder.
3. Factitious disorder presents with somatic and/or psychologic symptoms that are consciously controlled. It is presumed that the benefits associated with assuming a sick role unconsciously motivate the patient to maintain symptoms. Munchausen syndrome is an example of a chronic factitious disorder.

Distinguishing somatoform disorders from factitious disorders can be difficult: In the former, symptoms are associated with unconscious conflict, whereas in the latter the unconscious need to be cared for motivates the falsification of symptoms.

Although there are multiple theories regarding what factors most influence the cause and course of psychosomatic disorders, Engel's biopsychosocial approach to development and psychopathology offers a pragmatic organizational schema. Underlying temperamental factors, environmental stress, family issues, and individual psychodynamics all contribute, some more than others, depending on the situation. The notion of specific personality types leading to particular disorders has not been substantiated, although some studies have demonstrated family clustering of somatization disorder, antisocial personality disorder, and substance use

disorders.

It is extremely difficult to document the relative influence of psychologic factors in psychophysiologic conditions, and the mechanisms of influence for most of these disorders are not well studied. For instance, even a disorder such as *reflex sympathetic dystrophy*—which presents with chronic painful swelling in an extremity, decreased skin temperature, cyanosis, and delayed capillary refilling—may require psychotherapy to maximize function. Although there is no substitute for adequate medical evaluation, the pediatrician should have a low threshold for recommending proven adjunctive therapies for children with recurring physical symptoms.

Conversion disorder, the loss or alteration of physical functioning without a demonstrable organic illness, is a type of somatoform disorder that usually presents in adolescence or adulthood. However, numerous childhood cases have occurred. Conversion reactions usually start suddenly, can often be traced to a precipitating environmental event, and may end abruptly after a short duration. Voluntary musculature and organs of special sense are the most frequent target sites for expressions of psychologic conflict. Pseudoseizures are the most common conversion symptom, but such reactions may take many forms, including blindness, paralysis, diplopia, and gait disturbances. Physical examination often fails to reveal objective abnormalities. Histories may reveal a close relationship with a person who exhibited similar symptoms or a recent episode of actual illness. Deep tendon reflexes can be elicited in a paralyzed leg, and pupillary responses to light are noted in patients with hysterical blindness. Video electroencephalography and postictal serum prolactin levels are helpful in distinguishing pseudoseizures from seizures. Although conversion disorder is probably not genetically mediated, anxiety and chaotic disorganization patterns of disturbance are found in family members. Cultural factors affect the expression of illness and distress, and normative cultural behaviors should be ruled out before diagnosing conversion disorder. Follow-up studies suggest that about one third of children diagnosed with conversion disorder are later diagnosed with an explanatory medical disorder.

Hypochondriasis, preoccupation with the fear of having a serious illness, and *somatization disorder*, multiple somatic complaints

associated with generalized anxiety, are also somatoform disorders. Hypochondriasis and somatization disorder, like conversion disorder, are characterized by unconscious physiologic and psychologic conflict that is expressed as physical symptoms. Although community samples show that only half of children and adolescents questioned report at least one somatic symptom during the preceding 2 wk, these disorders are characterized by recurring symptoms. Because recurrent abdominal pain accounts for 2–4% of all pediatric visits and headaches account for 1–2%, a comprehensive social history and review of symptoms should be conducted with each case. Prevalence studies suggest that 11% of boys and 15% of girls have ongoing somatic symptoms. Most of these children do well with regular visits and reassurance, though some children and parents insist on unnecessary medical work-up. Children with multiple complaints, high levels of anxiety, and family dysfunction will require psychiatric referral.

Munchausen syndrome by proxy is a factitious disorder in which parents induce physical symptoms in their children. It is considered a form of child abuse, sometimes ending in death (also see Chapter 35). The signs and symptoms can be varied, including fractures, poisonings, persistent complaints of apnea, and unusual injuries. Therapy includes separation of the child from the abusing parent and further investigation, as in cases of child abuse.

Body dysmorphic disorder should be considered in patients presenting with preoccupation with imagined or minor abnormalities in physical appearance. The anxious obsession about physical appearance that characterizes body dysmorphic disorder is often associated with social limitations and dysphoria. The prevalence in adolescents and children is not known, although studies of adults with this diagnosis suggest frequent onset of symptoms during adolescence (also see Chapter 104).

Several general principles guide the management of children with psychosomatic disorders:

1. Assessment should include inquiries about past somatic symptoms and family members or acquaintances with similar symptoms because these may provide clues to symptom source. Potential reasons underlying the need for secondary gain can be garnered from a comprehensive social history. In particular, history of maltreatment, bereavement, or mood and anxiety symptoms should be inquired about. Responses to placebo administration are not reliable in differentiating somatoform disorders from organic conditions.
2. Because the symptoms of psychosomatic disorders are not within the child's conscious control, they are not acting or malingering, and attempting to talk them out of their symptoms or confronting them is contraindicated.
3. Early integration of pediatric and mental health assessment and treatment is important to prevent patients from seeking unnecessary work-up.
4. The child and family should be helped to live as normally as possible to avoid crippling psychologic invalidism. Emphasis should be placed on early return to school after acute illness, participation in recreational activities, and normal peer interactions. Parents should be informed that some children unconsciously use their symptoms to maintain dependency and that firm, gentle insistence on the fullest possible range of activities for the child is indicated.
5. Ideally, parents and children should understand the psychologic origins of symptoms; however, functional improvement may be achieved without full insight.
6. Psychotherapy for the child and family is often indicated, in addition to conservative pediatric management.
7. Psychoactive medications may be useful in treating symptoms of anxiety or depression, especially when these symptoms are prominent.
8. The physician should be alert for indications of psychosomatic or physical illness in parents, with which children may unconsciously identify; successful treatment of parental illness may be necessary to ensure a favorable outcome in the child.

Chapter 20 - Vegetative Disorders

The five disorders included under this appellation are classified in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, under Eating Disorders (rumination disorder and pica, along with bulimia and anorexia nervosa, which are discussed in Chapter 104), Elimination Disorders (encopresis and enuresis), and Sleep Disorders.

20.1 Rumination Disorder

Neil W. Boris
Richard Dalton

The hallmark of this disorder is a weight loss or failure to gain at the expected level because of repeated regurgitation of food without nausea or associated gastrointestinal illness. This rare disorder occurs more commonly in males and usually appears between 3 and 14 mo of age. It is potentially fatal; some reports indicate that up to one fourth of affected children die. There are psychogenic and self-stimulating ruminators. The former type occurs in infants with otherwise normal development, although there is often a disturbed parent-child relationship and the child may fail to thrive (Chapter 36). The self-stimulating variety is usually seen in mentally retarded individuals of any age and often occurs even in the presence of nurturing parents. The differential diagnosis should include congenital anomalies that affect the development of the gastrointestinal system and pyloric valve.

Behavioral treatment is directed toward positively reinforcing correct eating behavior and negatively reinforcing rumination. Adverse conditioning is often used. Parent counseling and family therapy are often necessary to manage underlying conflicts and to help educate the parents about appropriate approaches to be taken toward the child and the problem.

20.2 Pica

Neil W. Boris
Richard Dalton

This eating disorder involves repeated or chronic ingestion of non-nutritive substances, which may include plaster, charcoal,

clay, wool, ashes, paint, and earth. Although tasting or mouthing of objects is normal in infants and toddlers, pica after the 2nd yr of life needs investigation. Mental retardation and lack of parental nurturing (psychologic and nutritional) are predisposing factors, and pica appears to be more common in children with autism and other brain-behavior disorders such as Kleine-Levin syndrome. Persistent pica is also often associated with family disorganization, poor supervision, and psychologic neglect. Pica appears to be more prevalent in the lower socioeconomic classes. It usually remits in childhood but can continue into adolescence and adulthood. In particular, geophagia (eating of earth) is associated with pregnancy and is not seen as abnormal in some cultures. Children with pica are at an increased risk for lead poisoning (Chapter 703), iron-deficiency anemia (Chapter 447), and parasitic infections (see Part XVI , Sections 12 and 13). Screening for lead intoxication, iron-deficiency anemia, and parasitic infestation is always indicated.

20.3 Enuresis (Bed-wetting)

Neil W. Boris
Richard Dalton

Enuresis is defined as the voluntary or involuntary repeated discharge of urine into clothes or bed after a developmental age when bladder control should be established. Most children with a mental age of 5 have obtained bladder control during the day and night. The diagnosis of enuresis is made when urine is voided twice a week for at least 3 consecutive months or clinically significant distress occurs in areas of the child's life as a result of the wetting (see also Chapters 5 and 535). The prevalence of enuresis at age 5 yr is 7% for males and 3% for females. At age 10 yr, it is 3% for males and 2% for females, and at age 18 yr, it is 1% for males and extremely rare in females. Twin studies show that there is a marked familial pattern: A 68% concordance rate in monozygotic twins and a 36% concordance rate in dizygotic twins has been documented. However, linkage studies have implicated multiple chromosomes, particularly chromosome 22, and varying patterns of transmission appear likely.

Etiology.

Beyond genetic factors, the cause of enuresis likely involves a complex web of physiologic and, perhaps, psychologic factors. Children with nocturnal enuresis, for instance, may both hyposecrete arginine vasopressin (AVP) generally and be less responsive to the lower urine osmolality associated with fluid loading. Independent evidence suggests that tubular sodium-potassium exchange in the kidney, partly influenced by AVP secretion, is associated with nocturnal enuresis. Evidence also suggests that AVP receptor function in the tubule may be a key factor in the pathophysiology of the disorder. On the other hand, there may also be associations between sleep and enuresis. Although enuresis may occur at any stage of sleep, there is some support for a relationship between sleep architecture, diminished capacity to be aroused from sleep, and abnormal bladder function in enuretics.

The relationship between enuresis and psychologic functioning also appears complex. Large-scale studies reveal that older enuretic children have a higher incidence of psychopathology generally than non-enuretic children, though no single disorder accounts for the group differences. Smaller studies suggest that children with attention-deficit/hyperactivity disorder more commonly are enuretic than age-matched comparison children. Secondary enuresis is associated with life stress and/or traumatic experiences, particularly in children who were late in first achieving nighttime dryness. The pediatrician should inquire about stressful events with all

children who present with secondary enuresis.

Clinical Manifestations.

Bed-wetting may be divided into the persistent (primary) type, in which the child has never been dry at night, and the regressive (secondary) type, in which a child who has been continent for 6 mo or more then begins to wet the bed. Primary enuresis represents approximately 90% of all cases. Further classification involves *nocturnal* enuresis (voiding urine at night), and *diurnal* enuresis (voiding urine while awake). Primary nocturnal enuresis is the most common and well studied subtype. Diurnal enuresis is more common in girls and rarely occurs after the age of 9 yr. The most common cause of daytime enuresis in the preschool child is waiting until the last minute to void urine (micturition deferral). In addition to micturition deferral, etiologic factors to consider in diurnal enuresis include a urinary tract infection, chemical urethritis, associated constipation, diabetes, and giggle or stress incontinence. Children with both nocturnal and diurnal enuresis, especially in the presence of voiding difficulties, are more likely to have abnormalities of the urinary tract, and ultrasonography or uroflowmetry is indicated for these cases. Otherwise anatomic abnormalities are rarely associated with either nocturnal or diurnal enuresis and invasive or costly studies are contraindicated. A urinalysis and urine culture will rule out both infectious cause and the elevated urine osmolality associated with diabetes.

Treatment.

Management of the child with enuresis should begin with behavioral treatment. General guidelines for a first-line approach would be as follows:

1. It is important to enlist the cooperation of the child to deal with the problem. Rewarding the child for being dry at night is a useful step. The child or parent can chart the dry nights, and, with each dry night, a small reward can be given. More substantial rewards should be given for increasing success.
2. The child should void before retiring.
3. Waking the child repeatedly to take him or her to the bathroom is not generally useful and may further engender or aggravate anger in child or parents. Some data indicate that enuretic children are more difficult to awaken than age-matched peers. However, using an alarm clock to wake the child once 2–3?hr after falling asleep is indicated.
4. Punishment or humiliation of the child by parents or others should be strongly discouraged.

One study showed that consistent dry bed training (as earlier) with positive reinforcement has a success rate of 85% or more. The use of conditioning devices (e.g., an alarm that rings when the child wets a special sheet) also is often helpful in training the child to improve bladder capacity and avoid enuresis. In effect, these devices provide a consistent mode for behavioral retraining. Again, consent of the child should be a prerequisite for use of such a device. Bell and pad alarm systems have a success rate of approximately 75% across many studies, with relapse rates that are lower than those with pharmacologic intervention. These devices are simple and cost-effective. However, psychotherapy for traumatized children with secondary enuresis may be indicated, especially when behavioral training has failed and traumatic experiences temporally associated with the onset of enuresis are noted.

Pharmacotherapy for enuresis is second-line treatment and should be reserved for those patients who have failed behavioral treatment. Head-to-head comparison studies of the bell and pad versus imipramine and desmopressin acetate (DDAVP) reveal significantly lower relapse rates for the bell and pad, although the initial response rates are similar. Imipramine (Tofranil) at a maximum dosage of 2.5?mg/kg/24?hr before bedtime has shown a success rate of approximately 50%, with a relapse rate of 30% or more even after 6 mo of treatment. Imipramine is associated with cardiac conduction disturbances and is deadly in overdose. DDAVP can be administered orally or intranasally at bedtime. The fast action of DDAVP suggests a role for special occasions (such as overnights) when rapid control of enuresis is desired. Unfortunately, the relapse rate upon discontinuation of DDAVP is very high, and 1 month of treatment typically costs as much as

---

a bell and pad system (which can be used for several months as necessary). DDAVP is also associated with rare side effects of hyponatremia and water intoxication, with resulting seizures.

20.4 Encopresis

Neil W. Boris
Richard Dalton

Encopresis refers to the passage of feces into inappropriate places after a chronologic age of 4 yr (or equivalent developmental level). Subtypes include encopresis with constipation and overflow incontinence (retentive encopresis) and encopresis without constipation and overflow incontinence (nonretentive). Encopresis may persist from infancy onward (e.g., primary) or may appear after successful toilet training (e.g., secondary). About two thirds of encopresis cases are of the retentive type and associated with chronic constipation; it is less clear what percentage of cases are primary versus secondary. In children younger than 4 yr of age, the male:female ratio for chronic constipation is 1:1. In the school-aged child, however, encopresis is more common in males, though good epidemiologic studies are lacking.

Clinical Manifestations.

The first consideration in managing encopresis is assessment of fecal retention. A positive rectal examination is sufficient to document fecal retention, but a negative rectal examination in the presence of encopresis requires plain abdominal roentgenograms. The presence of fecal retention is evidence of chronic constipation, and treatment will require active constipation management (Chapter 287).

Many children with encopresis present with abnormal anal sphincter physiology as documented either by electromyography or difficulty in defecating a rectal balloon. The inability to defecate a balloon at presentation is associated with poorer response to treatment. Abnormal anal sphincter function is a marker for chronic constipation; children with this pathology do not appear to have a higher incidence of behavioral or psychiatric disorders than those without. However, a chart review study suggests that primary encopresis in boys is associated with global developmental delays and enuresis, whereas secondary encopresis is associated with high levels of psychosocial stressors and conduct disorder. Associated behavioral or psychiatric problems obviously may complicate the treatment of encopresis—especially when parents respond to soiling with retaliatory, punitive measures and children become angry, ashamed, and resistant to intervention. School performance and attendance may be secondarily affected as the child becomes the target of scorn and derision from schoolmates because of the offensive odor.

Treatment.

The standard treatment approach to encopresis begins with clearance of impacted fecal material and short-term use of mineral oil or laxatives to prevent further constipation. Concomitant behavioral management is also indicated. The focus of behavioral treatment should be on compliance with regular postprandial toilet sitting and adoption of a high-fiber diet. On some occasions, manual disimpaction is required before the treatment can begin; rarely megacolon is observed and referral to a gastroenterologist is required. Several studies suggest that once impacted stool is removed, the combination of constipation management and simple behavior therapy is successful in the majority of cases, though it is often a period of months before soiling stops completely. However, compliance may wane and failure of this standard treatment approach sometimes requires more intensive intervention with a special emphasis on adherence to a high-fiber diet and family support for behavior change. Parents should be actively encouraged to issue rewards for compliance to the child from the outset of treatment and to avoid power struggles with the child. Keeping records of the child's progress is necessary. In cases where behavioral or psychiatric problems are evident, group or individual psychotherapy may be necessary.

Biofeedback, which is used to train the anal sphincter muscle, has been helpful in some cases but controlled trials do not suggest higher rates of improvement as compared to the standard treatment regimen. Long-term laxative use is contraindicated. Several case reports suggest improvement in some children on tricyclic antidepressants, though there is not enough data to warrant regular use of these drugs, particularly given their narrow therapeutic window and association with cardiac dysrhythmias. Furthermore, tricyclic antidepressants often cause or exacerbate constipation and should be avoided in children with retentive encopresis. The few long-term follow-up studies suggest that encopresis eventually resolves in most children, regardless of treatment approach.

20.5 Sleep Disorders

Judith A. Owens

General Considerations.

In order to evaluate sleep problems, it is important to first have an understanding of what constitutes "normal" sleep in children and adolescents. Sleep disturbances, as well as many characteristics of sleep itself, have some distinctly different features in children from sleep and sleep disorders in adults. In addition, sleep architecture and sleep patterns and behaviors change significantly across the age spectrum from infancy to preschool to adolescence. A summary of some of the more important normal developmental changes in children's sleep is found in Table 20–1 .

Most sleep problems in children may be broadly conceptualized as resulting from either inadequate duration of sleep for age (insufficient sleep *quantity*) or disruption and fragmentation of sleep (poor sleep *quality*). Insufficient sleep is usually the result of difficulty initiating (delayed sleep onset) and/or maintaining sleep (prolonged night wakings), whereas sleep fragmentation most often results from frequent, repetitive, and brief arousals during sleep. Inadequate sleep duration, especially in older children and adolescents, may also represent a conscious lifestyle decision to sacrifice sleep in favor of competing priorities such as homework and social activities. The underlying causes of sleep onset delay/prolonged night wakings or sleep fragmentation may in turn be related to primarily behavioral factors (e.g., bedtime resistance resulting in shortened sleep duration) and/or medical causes (e.g., obstructive sleep apnea causing frequent brief arousals).

As in adults, both insufficient quantity and poor quality of sleep in children usually result in *excessive daytime sleepiness* and decreased daytime alertness levels. However, sleepiness in children may not be immediately recognizable as drowsiness, yawning, and the other "classic" manifestations of sleepiness

TABLE 20.5-1 -- Normal Developmental Changes in Children's Sleep

Age Category	Average Sleep Duration (24?hr)	Sleep Patterns	Additional Variables Impacting on Sleep	Sleep Disorders

Newborns (0–3 mo)	16–20?hr	1 to 4?hr sleep periods followed by 1 to 2?hr awake periods Amount daytime sleep = amount nighttime sleep	Prematurity: few differences in sleep development Birth trauma associated with sleep disruption Breast-fed, shorter sleep periods	Colic Apnea of infancy
Infants (3–12 mo)	14–15?hr total at 4 mo; 13–14?hr total at 6 mo (11?hr/night; 3?hr in 2 naps/day) Nap for 2–4?hr/day at 9 to 12 mo	Sleep periods 3–4?hr first 3 mo; 6–8?hr periods at 4–6 mo; day/ night differentiation develops 6 wk to 3 mo 70–80% “settle” (sleep through the night) at 9 mo	Self-soothing skills develop starting at 3 mo; may “signal” night wakings (crying) to parents Settling and night wakings influenced by parenting, feeding practices Co-sleeping common	Sleep onset association disorder/night wakings Rhythmic movement disorders (head banging, body rocking)
Toddlers (1–3 yr)	12–14?hr total Nap 1.5–3.5?hr (1 nap/day)	Night wakings often resume	Nighttime fears develop; transitional objects, bedtime routines important	Sleep onset association disorder Limit setting sleep disorder/bedtime resistance
Preschool (3–6 yr)	11–12?hr Napping declines; most stop by age 5 yr	Night waking in about 20%	Napping patterns influenced by parental, school practices Sleep problems may become chronic	Limit setting sleep disorder Sleepwalking Sleep terrors Obstructive sleep apnea
Middle childhood (6–12?yr)	10?hr	Low levels daytime sleepiness Increased discrepancy school/non-school night sleep amounts	School and behavior problems may be related to sleep problems Stressful events affect sleep; poor sleep affects coping skills	Nightmares Anxiety-related sleep onset delay Insufficient sleep
Adolescence (>12 yr)	9?hr ideal; 7?hr actual	Often irregular; influence of lifestyle; later bedtimes/earlier rise times	Phase delay at puberty; daytime alertness decreases at mid-puberty	Insufficient sleep Delayed sleep phase Narcolepsy Restless legs syndrome/periodic limb movement disorder

that occur in adults. Instead, it often takes the form of mood disturbances, behavioral problems such as hyperactivity and poor impulse control, and neurocognitive dysfunction including inattention and impaired vigilance that, over time, may ultimately result in significant social, school, and learning problems.

Parasomnias (see below), which are episodic sleep behaviors such as sleepwalking and enuresis, constitute another category of sleep disorders occurring in children. *Circadian rhythm disorders*, such as delayed (later sleep onset and rise times) sleep phase, in which normal sleep-wake patterns are disturbed, and *primary disorders of excessive daytime sleepiness*, which are characterized by abnormal regulation of sleep and wakefulness (e.g., narcolepsy), are covered in more detail under adolescent sleep.

Certain pediatric populations are relatively more vulnerable to developing sleep problems on either an acute or chronic basis. These include children with medical problems, including chronic illnesses such as cystic fibrosis and rheumatoid arthritis and acute illnesses such as otitis media; children on medications that have stimulant (e.g., methylphenidate), sleep-disrupting (e.g., some asthma medications), or daytime sedating (e.g., some anticonvulsants) effects; hospitalized children; and children with a variety of psychiatric disorders, including attention-deficit/hyperactivity disorder (ADHD), depression, and anxiety disorders. Children with neurologic disorders may be more prone to nocturnal seizures, as well as other sleep disruptions, and children with blindness and developmental delay syndromes (e.g., autism/pervasive developmental delay) are at increased risk for severe sleep onset difficulty and night wakings, as well as circadian rhythm disturbances.

Health Supervision.

Sleep disturbances are one of the most common issues raised by parents during health supervision, and it is estimated that upwards of 25% of children experience a

significant sleep problem at some point during childhood. Although many sleep problems in infants and children are transient and self-limited in nature, certain intrinsic and extrinsic risk factors (difficult temperament, acute or chronic illness, maternal depression, family stress, etc.) may predispose a given child to develop a more chronic sleep disturbance. Inadequate or poor sleep in children may have negative consequences on a host of functional domains, including mood, behavior, learning, and health outcomes. Furthermore, the impact of childhood sleep problems is intensified by their direct effect on parents' sleep, resulting in daytime fatigue, mood disturbances, and a decreased level of effective parenting.

Therefore, it is especially important for pediatricians to both screen for and recognize sleep disorders in children and adolescents during health encounters. In addition, the well child visit is an opportunity to educate parents about normal sleep in children and to teach them strategies to prevent sleep problems from either developing in the first place (primary prevention), or from becoming chronic if problems already exist (secondary prevention). Developmentally appropriate *screening* for sleep disturbances should take place in the context of every well child visit and should include a range of potential sleep problems; one simple sleep screening algorithm, the “BEARS,” is outlined in Table 20–2 . Because parents may not always be aware of sleep problems, especially in older children and adolescents, it is also important to question the child directly about sleep concerns. The recognition and evaluation of sleep problems in children requires both an understanding of the association between sleep disturbances and daytime consequences, such as irritability, inattention, and poor impulse control, and familiarity with the developmentally appropriate differential diagnoses of common presenting sleep complaints (difficulty initiating and maintaining sleep, episodic nocturnal events, etc.). In particular, an assessment of sleep patterns and possible sleep problems should be part of the initial evaluation of every child presenting with behavioral and/or academic problems, especially ADHD.

TABLE 20.5-2 -- BEARS Sleep Screening Algorithm

The “BEARS” instrument is divided into 5 major sleep domains, providing a comprehensive screen for the major sleep disorders affecting children inthe 2–18 year old age range. Each sleep domain has a set of age-appropriate “trigger questions” for use in the clinical interview.

B = Bedtime problems

E = Excessive daytime sleepiness

A = Awakenings during the night

R = Regularity and duration of sleep

S = Snoring

Examples of Developmentally Appropriate Trigger Questions

	Toddler/Preschool (2–5 yr)	*School-aged (6–12 yr)*	*Adolescent (13–18 yr)*
1) **B**edtime problems	Does your child have any problems going to bed? Falling asleep?	Does your child have any problems at bedtime? (P) Do you have any problems going to bed? (C)	Do you have any problems falling asleep at bedtime? (C)
2) **E**xcessive daytime sleepiness	Does your child seem over tired or sleepy a lot during the day? Does she still take naps?	Does your child have difficulty waking in the morning, seem sleepy during the day or take naps? (P) Do you feel tired a lot? (C)	Do you feel sleepy a lot during the day? in school? while driving? (C)
3) **A**wakenings during the night	Does your child wake up a lot at night?	Does your child seem to wake up a lot at night? Any sleepwalking or nightmares? (P) Do you wake up a lot at night? Have trouble getting back to sleep? (C)	Do you wake up a lot at night? Have trouble getting back to sleep? (C)
4) **R**egularity and duration of sleep	Does your child have a regular bedtime and wake time? What are they?	What time does your child go to bed and get up on school days? Weekends? Do you think he/she is getting enough sleep? (P)	What time do you usually go to bed on school nights? Weekends? How much sleep do you usually get? (C)
5) **S**noring	Does your child snore a lot or have difficulty breathing at night?	Does your child have loud or nightly snoring or any breathing difficulties at night? (P)	Does your teenager snore loudly or nightly? (P)

P = Parent; C = Child.

Effective *preventative measures* may include educating parents of newborns about normal sleep amounts and patterns; suggesting that parents put their 4–6-month-old infants to bed “drowsy but awake” in order to avoid dependence on parental presence at sleep onset and to foster the infants' ability to “self-soothe,” discussing the importance of regular bedtimes, bedtime routines, and transitional objects for toddlers; and providing parents and children with basic information about good “sleep hygiene” (Table 20–3) and adequate sleep amounts.

It is important also to consider the cultural and family context within which sleep problems in children occur (Chapter 3). For example, *co-sleeping* of infants and parents is a common and accepted practice in many ethnic groups, including African-Americans, Hispanics, and Southeast Asians. Therefore, the goal of independent “self-soothing” in young infants may not be shared by these families. On the other hand, the institution of co-sleeping by parents as an attempt to address a child's underlying sleep problem, rather than as a lifestyle choice, is likely to yield only a temporary respite from the problem and may set the stage for more significant

sleep issues.

Behavioral Sleep Disorders.

Sleep problems, like many behavioral issues in children, are often primarily defined by parental concerns rather than by objective criteria. Many of the behaviorally based sleep disorders are the result of the interaction between normal developmental sleep changes, as outlined above, and parental response to those changes. For example, one of the most common sleep disorders found in infants and toddlers is *sleep onset association disorder*. In this disorder, the child learns to fall asleep only under certain conditions or associations, such as being rocked or fed, and does not develop the ability to self-soothe. During the night, when the child experiences the type of brief arousal that normally occurs at the end of a sleep cycle (every 90–120?min) or awakens for other reasons, he or she is not able to get back to sleep without those same conditions being present. The infant then “signals” the parent by crying (or coming into the parents' bedroom if the child is no longer in a crib) until the necessary associations are provided. Thus, the problem is one of prolonged night waking resulting in insufficient sleep (for both child and parent!).

The treatment approach to sleep onset association disorder typically involves a program of withdrawal of parental assistance at sleep onset and during the night (systematic ignoring). In older infants, the introduction of more appropriate sleep associations that will be readily available to the child during the night (transitional objects such as a blanket or toy) in addition to positive reinforcement (e.g., stickers for remaining in bed) is often beneficial. The goal is to allow the infant or child to develop skills in self-soothing during the night, as well as at bedtime. “Graduated extinction” is a more gradual process of weaning the child from dependence upon parental presence that utilizes periodic “checks” by the parents at successively longer time intervals during the sleep-wake transition. If the child has become habituated to awaken for nighttime feedings (“learned hunger”), then these feedings should be slowly eliminated. Parents must be consistent in applying behavioral programs to avoid inadvertent, intermittent reinforcement of night wakings; they should also be forewarned that crying behavior frequently temporarily escalates at the beginning of treatment (“post-extinction burst”).

In contrast, *limit setting sleep disorder*, a disorder most common in children preschool-aged and older, is characterized by difficulty falling asleep and bedtime resistance (“curtain calls”) rather than night wakings. The prolonged sleep onset delay results in inadequate sleep duration. Most commonly, this disorder develops from a parent's inability or unwillingness to set consistent bedtime rules and enforce a regular bedtime, often exacerbated by the child's oppositional behavior. In some cases, however, the child's resistance at bedtime is due to an underlying problem in falling asleep caused by other factors (e.g., medical conditions such as asthma or medication use, a sleep disorder such as Restless Legs syndrome, or anxiety) or a mismatch

TABLE 20.5-3 -- **Basic Principles of Sleep Hygiene for Children**

1. **Have a set bedtime and bedtime routine** for your child.
2. **Bedtime and wake-up time should be about the same time on school nights and non-school nights**. There should not be more than about an hour difference from one day to another.
3. **Make the hour before bed shared quiet time**. Avoid such high-energy activities as rough play, and stimulating activities such as watching TV or playing computer games just before bed.
4. **Don't send your child to bed hungry**. A *light* snack (such as milk and cookies) before bed is a good idea. Heavy meals within an hour or two of bedtime, however, may interfere with sleep.
5. **Avoid products containing caffeine for at least several hours before bedtime**. These include caffeinated sodas, coffee, tea, and chocolate.
6. **Make sure your child spends time outside every day** whenever possible and is involved in regular exercise.
7. **Keep your child's bedroom quiet and dark**. A low-level nightlight is acceptable for children who find completely dark rooms frightening.
8. **Keep your child's bedroom at a comfortable temperature** during the night (less than 75 degrees).
9. **Don't use your child's bedroom for time-out or punishment**.
10. **Keep the television set out of your child's bedroom.** Children can easily develop the bad habit of “needing” the TV to fall asleep. It's also much more difficult to control your child's TV viewing if the set is in the bedroom.

TABLE 20.5-4 -- **Differentiation of Episodic Nocturnal Phenomena**

Characteristics	**Sleepwalking**	**Sleep Terrors**	**Nightmares**	**Nocturnal Seizures**
Timing During Night	First third	First third	Last third	Variable; often at sleep-wake transition
Sleep Stage	SWS	SWS	REM	Non-REM>REM
Clinical Description				
1. Displacement from bed	Usual during event	May occur during event	Occasional after event	Unusual
2. Autonomic arousal/agitation	Low to mild	High to extreme	Mild to high	Variable
3. Stereotypic/repetitive behavior	Variable; complex behaviors	Variable	None; little motor behavior	Common
4. Arousal threshold	High; agitated if awakened	High; agitated if awakened	Low; awake and agitated after event	High; awake and confused after event
5. Associated daytime sleepiness	None	None	Yes, if night waking prolonged	Probable

Recall of Event Incidence	None or fragmentary Common (20% at least one episode; 1 to 6% chronic)	None or fragmentary Rare (1 to 6%); 10% of sleepwalkers	Frequent, vivid Very common	None Infrequent
Family History	Common	Common	No	Variable

REM = rapid eye movement; SWS = slow wave sleep.

between the child's intrinsic circadian rhythm (“night owl”) and parental expectations.

Successful treatment of limit setting sleep disorder generally involves a combination of decreased parental attention for bedtime-delaying behavior, establishment of bedtime routines, and positive reinforcement (e.g., sticker charts) for appropriate behavior at bedtime. Older children may benefit from being taught relaxation techniques to help themselves fall asleep more readily.

Parasomnias.

Parasomnias are defined as episodic nocturnal behaviors that often involve cognitive disorientation and autonomic and skeletal muscle disturbance. Many of the parasomnias are associated with relative central nervous system immaturity and, thus, tend to be much more common in children than adults and to abate with age. The *partial arousal parasomnias*, which include sleepwalking and sleep terrors, have several features in common. Because they typically occur at the transition out of Stage 4 or slow wave sleep (SWS), partial arousal parasomnias have clinical features of both the awake (ambulation, vocalizations) and the sleeping (high arousal threshold, unresponsiveness to the environment) state, and there is usually amnesia for the events. They are more common in preschoolers and school-aged children because of the relatively higher percentage of SWS in younger children. Furthermore, any factors that are associated with an increase in the relative percentage of SWS (certain medications, previous sleep deprivation) may increase the frequency of events in a predisposed child. The typical timing of partial arousal parasomnias during the first 2?hr of sleep is related to the predominance of SWS in the first third of the night. Finally, there appears to be a genetic predisposition for both sleepwalking and night terrors.

In contrast, *nightmares*, which are much more common than the partial arousal parasomnias but are often confused with them, are concentrated in the last third of the night, when rapid eye movement of REM sleep is most prominent. Partial arousal parasomnias may also be difficult to distinguish from nocturnal seizures. Table 20–4 summarizes similarities and differences among these four nocturnal arousal events.

The treatment of partial arousal parasomnias generally involves parental education and reassurance, avoidance of exacerbating factors such as sleep deprivation, and, particularly in the case of sleepwalking, institution of safety precautions. Pharmacotherapy or psychotherapy is rarely indicated. However, frequent and persistent nightmares in a child warrant further investigation regarding possible trauma, such as sexual abuse, and/or evaluation for a more global anxiety disorder.

Rhythmic movement disorders, including body rocking and head banging, are parasomnias that are much more common in the first year of life and generally disappear by age 4 yr. They occur largely during sleep-wake transition, and are characterized by repetitive, stereotypic movements involving large muscle groups. Although occasionally associated with developmental delay, the vast majority occur in normal children and do not result in physical injury to the child. Treatment is generally parental reassurance.

Sleep in Adolescents.

Although sleep patterns and the types of sleep disorders most commonly found in adolescents share features with those of both younger children and of adults, the physiologic changes that occur during puberty and the developmental challenges of adolescence contribute to a number of unique aspects of adolescent sleep. In order to appreciate the impact of these physiologic and psychologic changes, it is

important first to consider them in the context of human sleep regulation and some of the basic principles that govern sleep and wakefulness. The first principle relates to those factors that determine the relative level of sleepiness or alertness occurring throughout a given 24-hr time period; these include both intrinsic *circadian* factors or rhythms (“biologic time clock”) and *homeostatic* factors (duration and quality of previous sleep as well as time awake since the last sleep period). For example, there are two periods of clock-dependent maximum sleepiness (“circadian troughs”) and maximum alertness that occur during the course of a 24-hour day. The degree of sleepiness experienced during a given circadian trough period, however, is also influenced by the relative sleep need existing at the time (e.g., is increased in the sleep-deprived individual). Intrinsic circadian rhythms are in turn affected to a degree by external time cues or “zeitgebers” (e.g., timing of meals, alarm clocks, etc.), but they are most sensitive to light/darkness signals, which switch the body's production of the hormone melatonin off (light) or on (dark).

A second important principle of sleep regulation relates to the consequences of the failure to meet basic sleep needs. Individual sleep needs are dependent upon a number of factors, including age and the amount of sleep obtained in the preceding period. Inadequate sleep on a chronic basis results in what is called a *sleep debt*. If the sleep debt becomes large enough and is not voluntarily paid back, the body may respond by overriding voluntary control of wakefulness, resulting in periods of decreased alertness, dozing off, and napping. In addition, the sleep-deprived individual may experience very brief (several seconds) repeated daytime *microsleeps* of which he or she may be completely unaware, but which nonetheless may result in significant lapses in attention and vigilance. This becomes a particularly problematic issue in adolescents, who may be operating motor vehicles (“drowsy driving”).

FEATURES OF ADOLESCENT SLEEP.

Adolescent sleep needs are not dramatically different from sleep needs of preadolescents, about 9 hours per night. In contrast, most adolescents obtain on the order of 7 to 7½?hr of sleep per night, which results in a considerable sleep debt over time. Part of the reason for this insufficient sleep relates to pubertal influences on melatonin and circadian sleep/wake cycles, which cause a relative *phase delay* (later sleep onset and wake times). Not only are adolescents less likely to fall asleep early, but the start time of many high schools precludes a corresponding later wake time in the morning. In addition, many adolescents have highly irregular sleep/wake patterns from weekday to weekend; when coupled with a physiologic tendency to develop decreased daytime alertness levels in mid to late puberty, this all results in considerable increase in sleepiness levels and consequent impairment in mood, attention, memory, behavioral control, and academic performance.

Adolescents may also suffer from a number of sleep disorders, some of which are detailed in other chapters. Studies have suggested that the prevalence of significant sleep problems in adolescents is high (at least 20%) and that particular groups of adolescents, such as those with chronic medical or psychiatric problems, may be at increased risk. As would be expected, *circadian rhythm* disturbances, especially *delayed sleep phase syndrome*, are prominent in adolescence; these are sometimes treated with a combination of exogenous melatonin and bright light therapy to help “reset” the clock. Teenagers with a severely delayed sleep phase (greater than 3 to 4?hr) may benefit from a technique called chronotherapy, in which the sleep onset and wake times are successively delayed over a period of time until the new sleep onset time coincides with the desired bedtime.

Psychophysiologic insomnia (difficulty initiating and/or maintaining sleep) is also common in adolescents. In this disorder, the individual develops conditioned anxiety around difficulty falling or staying asleep, which leads to heightened arousal and further compromises the ability to sleep. Treatment usually involves educating the adolescent about principles of sleep hygiene (Table 20–5), instructing him or her to use the bed for sleep only and to get out of bed if unable to fall asleep (stimulus control), restricting time-in-bed to the actual time asleep (sleep restriction), and teaching relaxation techniques to reduce anxiety. Hypnotic medications are rarely needed.

Narcolepsy is a primary disorder of excessive daytime sleepiness that affects an estimated 0.05% of Americans. Narcolepsy often presents with symptoms in adolescence, but usually goes unrecognized and undiagnosed until adulthood. In about 25% of cases, there is a family history of narcolepsy; secondary narcolepsy following brain injury or in association with other medical illnesses may also occur. The cardinal and usual initial presenting feature of narcolepsy is repetitive episodes of profound sleepiness that may occur both at rest and during periods of activity (talking, eating, etc.). These “sleep attacks” may be very brief (microsleeps), resulting primarily in lapses in attention and in mood disturbances. Thus, patients with narcolepsy may be initially misdiagnosed with a psychiatric disorder such as ADHD or depression. Other features that may occur in narcolepsy include cataplexy (sudden loss of total body or partial muscle tone, usually in response to an emotional stimulus), hypnogogic (at sleep onset) and/or hypnopompic (on waking) visual, auditory or tactile hallucinations, and sleep paralysis (temporary loss of voluntary muscle control) at sleep onset or offset. The “gold standard” of diagnosis is overnight polysomnography followed by a multiple sleep latency test (MSLT). The MSLT involves a series of opportunities to nap during which narcoleptics demonstrate a pathologically shortened sleep onset latency, as well as periods of REM sleep occurring immediately after sleep onset. The treatment of narcolepsy generally involves a combination of medications to combat daytime sleepiness (stimulants) and REM sleep suppressants to prevent cataleptic attacks.

Restless Legs syndrome (RLS)/periodic limb movement disorder (PLMD) is a sleep disorder that is characterized by what is often described as uncomfortable “creeping” or “crawling” sensations

TABLE 20.5-5 -- **Basic Principles of Sleep Hygiene for Adolescents**

1. **Wake up and go to bed at about the same time** every night. Bedtime and wake time should not differ from school to non-school nights by more than approximately an hour.
2. **Avoid sleeping in on weekends** to “catch-up” on sleep. This makes it more likely that you will have problems falling asleep.
3. If you take **naps**, they should be **short** (no more than an hour) and **scheduled in the early to mid-afternoon**. However, if you have a problem with falling asleep at night, **napping** during the day may make it worse and should be avoided.
4. **Spend time outside** every day. Exposure to sunlight helps to keep your body's internal clock on track.
5. **Exercise regularly**. Exercise may help you fall asleep and sleep more deeply.
6. **Use your bed for sleeping only**. Don't study, read, listen to music, watch TV, etc., on your bed.
7. Make the 30–60 minutes before bedtime a **quiet or wind-down time**. Relaxing, calm, enjoyable activities such as reading a book or listening to calm music help your body and mind slow down enough to let you get to sleep. Don't study, watch exciting/scary movies, exercise, or get involved in “energizing” activities just before bed.
8. Eat regular meals and **don't go to bed hungry**. A light snack before bed is a good idea; eating a full meal in the hour before bed is not.
9. **Avoid** eating or drinking products containing **caffeine** from dinner time on. These include caffeinated sodas, coffee, tea, and chocolate.
10. **Do not use alcohol**. Alcohol disrupts sleep and may cause you to awaken throughout the night.
11. **Smoking disturbs sleep.** Don't smoke at least one hour before bed (and preferably, not at all!).
12. Don't use **sleeping pills, melatonin**, or other **over-the-counter sleep aids** to help you sleep unless specifically recommended by your doctor. These can be dangerous, and the sleep problems often return when you stop the medicine.

occurring primarily in the lower extremities and during periods of rest or inactivity (e.g., sleep onset), which are relieved by movement. In younger children, these sensations may be manifested as “growing pains.” The symptoms often result in significantly delayed sleep onset. RLS appears to have a genetic basis and

exacerbating factors include increased caffeine intake, iron deficiency (low ferritin), and pregnancy. Although the prevalence of RLS in adolescents is unknown, approximately 1 in 2000 adults has the disorder. RLS is thought to be related to decreased dopaminergic activity; pharmacologic treatment generally involves dopaminergic agents. Approximately 80% of patients with RLS also have repetitive rhythmic kicking movements of the lower extremities during sleep called periodic limb movements. The sleeper is usually unaware of the leg movements and of the resulting sleep fragmentation. Both RLS and PLMD may result in manifestations of significant daytime sleepiness, including inattention and hyperactivity. RLS is a clinical diagnosis; the diagnosis of PLMD requires polysomnography to detect the characteristic rhythmic movements of the anterior tibialis muscle group and frequent arousals.

Evaluation of Pediatric Sleep Problems.

The clinical evaluation of a child presenting with a sleep problem involves a careful medical history to assess for potential medical causes of sleep disturbances, such as allergies, concomitant medications, and acute or chronic pain conditions. A developmental history is important because of the aforementioned frequent association of sleep problems with severe developmental delay. Assessment of the child's current level of functioning (school, home, etc.) is key in evaluating possible mood, behavioral, and neurocognitive sequelae of sleep problems. Current sleep patterns, including usual sleep duration and sleep/wake schedule, are often best assessed with a sleep diary, in which parents record daily sleep behaviors for an extended period. A review of sleep habits, such as bedtime routines, daily caffeine intake, and the sleeping environment (temperature, noise level, etc.) may reveal environmental factors that contribute to the sleep problems.

Nocturnal symptoms that may be indicative of a medically based sleep disorder such as obstructive sleep apnea (loud snoring, choking/gasping, sweating) or periodic limb movements (restless sleep, repetitive kicking movements) should be elicited. However, an overnight sleep study is seldom warranted in the evaluation of a child with sleep problems unless there are symptoms suggestive of obstructive sleep apnea (Chapter 369) or periodic leg movements, unusual features of episodic nocturnal events, or daytime sleepiness that is unexplained.

Chapter 21 - Habit Disorders

Neil W. Boris
Richard Dalton

Habit disorders include tension-discharging phenomena, such as head banging, body rocking, thumb sucking, nail biting, hair pulling (trichotillomania), teeth grinding (bruxism), hitting or biting parts of one's own body, body manipulations, repetitive vocalizations, and air swallowing (aerophagia). Tics, which involve the involuntary movement of various muscle groups, are also included. Many children at various developmental points show repetitive patterns of movement that can be described as habits. Whether they are considered disorders depends on the degree to which they interfere with the child's physical, emotional, or social functioning. Some habit patterns may be learned by imitation of adults. Many begin as a purposeful movement that, for some reason, becomes repetitive, with the habit losing its original significance and becoming a means of discharging tension. For example, a child who has an eye irritation or is attempting not to shed tears might try closing the eyelids several times in rapid succession. This activity may become repetitive and incorporated into the child's behavior as an outlet for tension. Such symptoms are often reinforced by attention from parents or others. Other movements, such as rhythmic head banging and rocking in early life, can persist without parental reinforcement, occurring when the child is put to bed or is alone; these movements seem to provide a kind of sensory solace for the child. In many cases, children who exhibit head banging or rocking either have been neglected or have developmental delays. These movements represent a kind of internal stroking. Some children twist their hair or touch or play with parts of their bodies in repetitive ways. As these children become older, they may learn to inhibit some of their rhythmic habit patterns, particularly in social situations. In some cases, however, social anxiety can increase repetitive behaviors. The prevalence of habit disorders is not known. In part, this is because habit disorders are a heterogeneous group of disorders with varying causes. The natural course can vary, though children with mental retardation may be more refractory to treatment.

Teeth grinding, or *bruxism,* is quite common, can begin in the first 5 yr of life, and seems to be associated with daytime anxiety. Untreated bruxism may create problems with dental occlusion. Helping the child find ways to reduce anxiety may relieve the problem, though studies of psychologic treatment for bruxism are rare. Bedtime can be made more enjoyable and relaxed by reading or talking with the child, permitting review of fears or angers experienced during the day. Praise and other emotional support are useful at these times. To what degree bruxism is heritable is not known. Persistent bruxism requires referral to a dentist and may present as muscular or temporomandibular joint pain.

Thumb sucking is normal in infancy and toddlerhood. Older children who thumb suck may eventually affect alignment of the teeth. Like other rhythmic patterns of behavior, thumb sucking can be seen as a way of securing extra self-nurturance. The best strategy for dealing with thumb sucking is to provide the child with praise for substitute behaviors. Parents should ignore thumb sucking, if possible, while giving attention to more positive aspects of the child's behavior. When the child actively tries to restrain thumb sucking, he or she should be given praise and encouragement. The use of noxious agents (e.g., bitter salves) to control thumb sucking is not well studied and should be considered a second-line approach.

Tics involve repetitive movements of muscle groups and represent discharges of tension related to central nervous system electrochemical signals. Parts of the body most frequently involved are the

muscles of the face, neck, shoulders, trunk, and hands. There may be lip smacking and grimacing, tongue thrusting, eye blinking, throat clearing, and so on. Tics must be distinguished from petit mal or other nongeneralized seizure disorders. Seizure disorders are characterized both by transient inability to interact during periods of eye blinking or lip smacking or amnesia for the event. An electroencephalogram (EEG) may be necessary in some cases to distinguish tic disorders from seizure disorders. Tics can be distinguished from dyskinetic movements and dystonias by their discontinuation during sleep and by virtue of the conscious control that can be achieved for short periods. However, it is very difficult to continuously and consciously inhibit tics. In some cases, tics are transient; in others, the development of tics is temporally related to the use of dopaminergic agonists such as stimulant medications. When this happens, discontinuing the stimulant will usually, but not always, lead to remission of tics. Clinical experience suggests that about half of patients will not redevelop tics when a stimulant is restarted.

EEG findings and cognitive testing do not differentiate patients with tics from control subjects. Most children with simple motor tics do not require treatment, though some may experience associated problems including neuropsychologic dysfunction, academic underachievement, or low self-esteem. These associated problems may require psychotherapeutic intervention.

Gilles de la Tourette syndrome, which has a lifetime prevalence rate of 0.5/1,000 individuals, commonly presents in childhood. Fifty per cent of patients with Tourette syndrome have symptom onset prior to age 7. Tourette syndrome is characterized by a history of motor *and* vocal tics (though they do not have to be present concurrently for diagnosis). In many cases multiple tics or complex vocal sounds such as barking and grunting are present. Rarely, shouting obscene words is evident. Tourette syndrome is more common in the first-degree relatives of patients with Tourette syndrome than in the general population and affects boys three to four times more often than girls. It is more common in whites than in other races.

Children with Tourette syndrome often suffer from associated behavioral, emotional, and academic problems. In particular, these children have higher rates of obsessive-compulsive disorder (OCD), attention-deficit/hyperactivity disorder (ADHD), and oppositional-defiant disorder. The fact that Tourette disorder is highly co-morbid with these specific psychiatric disorders suggests dysfunction in particular regions of the brain.

Although the etiology of Tourette syndrome is uncertain, an interplay among genetic, neurobiologic, psychologic, and environmental factors is likely. Neuroimaging studies suggest that there is a lack of normal asymmetry within the striatum. The precipitation and worsening of tics by stimulant medication suggests dopaminergic involvement in tic and Tourette disorders. Single photon emission computed tomography scan data implicate dysfunction in dopamine receptor binding in severely affected children. In addition, just as with OCD, there is evidence to suggest that a subgroup of prepubertal children who suddenly develop Tourette syndrome suffer with a *pediatric autoimmune neuropsychiatric disorder associated with streptococcal infection* (PANDAS), in which antibodies to group A streptococcal infections cross react with basal ganglia tissue and subsequently precipitate symptoms. The diagnostic index of suspicion should be raised when symptoms develop precipitously after a streptococcal-like episode of pharyngitis in children. In many cases, tics or obsessions may flare after further episodes of infection. A thorough history and an antistreptolysin O (ASO) titer are indicated to confirm the presence of a PANDAS. Treatment of PANDAS includes acute and prophylactic antibiotic therapy. There may be a role for intravenous immunoglobulin during acute infection or even therapeutic plasma exchange for severely affected children, though data on these treatments are limited. Rarely, Lyme disease may also present with clinical manifestations of Tourette syndrome (see Chapter 204). Many environmental factors serve as emotional stressors, which also precipitate or increase tics and Gilles de la Tourette syndrome. Laboratory studies are nonspecific; up to 80% of patients with Tourette syndrome have nonspecific abnormal EEG findings. Abnormal amounts of various neurotransmitter metabolites as well as lower scores on verbal subscales of psychometric tests have been reported.

Treatment for Gilles de la Tourette syndrome should only occur after careful consideration of the functional limitations associated with each given child's symptoms, associated symptoms (e.g., ADHD, OCD, or oppositional tendencies), and risks and benefits of pharmacotherapy. In many cases, supportive management is all that is indicated. Children and families often gain support from organizations like the Tourette's Syndrome Association. Pharmacotherapy is indicated when tics interfere with social development or classroom function. There is some controversy over what agents are first-line treatments, though neuroleptics have the strongest track record in controlled trials. Haloperidol and pimozide, dopaminergic antagonists, have been shown to reduce the severity of tics by 65%. Because potentially severe side effects attend the use of both medications, most clinicians now use novel neuroleptics such as risperidone and olanzapine. Clonidine, an a_2 agonist, has also been shown to be effective in controlled trials. However, sedation and low blood pressure are associated with clonidine; the role for guanfacine (Tenex), which is less sedating, has not been firmly established (see Chapter 28.2). Botulinum toxin has also recently been shown to be effective for motor tics.

Some children with Tourette syndorme require medications aimed at obsessive-compulsive symptoms or attention and impulsivity problems. Unfortunately, psychostimulants may make tics worse in children with co-morbid Tourette disorder and ADHD. The physician must weigh the benefits of improvement in ADHD symptoms with the potential exacerbation of tics. Tourette disorder may persist throughout life; however, studies have shown a significant diminution in symptoms in adolescence and early adulthood in about two thirds of cases.

Chapter 22 - Anxiety Disorders

Brian Stafford
Neil W. Boris
Richard Dalton

Anxiety is a normal phenomenon that has evolutionary value for the species. Anxiety has both a physiologic component, mediated by the autonomic nervous system, and a cognitive and behavioral component, expressed in worrying and wariness. When anxiety becomes disabling, interfering with social interactions and development, a diagnosis should be made and intervention initiated. Separation anxiety disorder, childhood onset

social phobia, generalized anxiety disorder, obsessive-compulsive disorder (OCD), phobias, post-traumatic stress disorder (PTSD), and panic disorder are all defined by the occurrence of either diffuse or specific anxiety, often related to predictable situations or “cues.” As a group, anxiety disorders are the most common psychiatric disorders of childhood: epidemiologic data suggest that they occur in 5–18% of all children and adolescents. Anxiety disorders are often co-morbid with other psychiatric disorders (including a second anxiety disorder), and significant impairment in day-to-day functioning is not uncommon.

Because anxiety is both a normal phenomenon and, when highly activated, strongly associated with impairment, the pediatrician will be required to differentiate normal from abnormal across development. Fortunately, anxiety has an identifiable developmental progression for most children. For instance, most infants exhibit stranger wariness or anxiety beginning at 7–9 mo of age. Furthermore, studies document that behavioral inhibition to the unfamiliar (e.g., withdrawal/fearfulness to novel stimuli associated with physiologic arousal) is evident in about 10–15% of the population at 12 mo of age and is moderately stable. Most children who display behavioral inhibition do not eventually develop impairing levels of anxiety. However, data from a cohort of behaviorally inhibited infants followed longitudinally revealed that both a family history of anxiety disorders and maternal over-involvement or enmeshment predicted later clinically significant anxiety problems. The infant who is excessively clingy and difficult to calm during pediatric visits should be followed for signs of increasing levels of anxiety.

Preschoolers typically develop specific fears related to the dark, to animals, and to imaginary situations. Preoccupation with orderliness and routines (so-called “just right” phenomena) also often take on an anxious quality for preschool children. Parental reassurance is usually sufficient to help the child through this period. Although most school-aged children give up the imaginary fears of early childhood, some replace them with fears of bodily harm or other worries. In adolescence, both social anxiety and general worrying (about school, friends, and family) are not uncommon.

Genetic or temperamental factors contribute more to the development of some anxiety disorders, whereas environmental factors are closely linked to the cause for others. Specifically, behavioral inhibition appears to be a heritable tendency and is linked with social phobia, generalized anxiety, and selective mutism. OCD and other disorders associated with OCD-like behaviors, such as Tourette and other tic disorders, tend to have high genetic risk as well (see Chapter 21). Environmental factors, such as parent-infant attachment and exposure to trauma, contribute more to separation anxiety disorder and PTSD. Even in those disorders associated with environmental risk, nature and nurture interact to create maladaptive behavior.

Separation anxiety disorder (SAD) is characterized by unrealistic and persistent worries of possible harm befalling primary caregivers, reluctance to go to school or sleep without being near the parents, persistent avoidance of being alone, nightmares involving themes of separation, numerous somatic complaints, and complaints of subjective distress. The first clinical sign of the disorder may not appear until third or fourth grade, typically after holidays, a period where the child has been home because of illness, or the stability of the family structure has been threatened by illness, divorce, or other calamity. In many cases, parents are unable to be assertive in returning the child to school. In these instances, the pediatrician should screen for parental depression or anxiety. Often referral for parental treatment or family therapy is necessary before separation anxiety and concomitant school refusal can be successfully treated.

A large percentage of children with SAD develop feelings of panic when they are coerced to separate from their parents. Children with SAD appear to have a higher than expected likelihood of developing panic disorder in adolescence. When a child reports recurring acute severe anxiety, antidepressant or anxiolytic medication is often necessary. After promising initial data, subsequent controlled studies of tricyclic antidepressants (e.g., imipramine) and benzodiazepines (e.g., clonazepam) have revealed that these agents are not generally effective. Alternatively, data supports the use of selective serotonin reuptake inhibitors (SSRIs; see Chapter 28.2). Individual and/or group cognitive behavioral therapy may also add benefit, though attention to the family context remains necessary.

Childhood-onset *social phobia* (SP) is characterized by excessive anxiety in social settings (including school) leading to social isolation. These children and adolescents often maintain the desire for involvement with family and familiar peers. The long-term course is variable, though good longitudinal studies are lacking. However, some children are very distressed by their inability to engage in meaningful relationships with peers and seek treatment. A family history of social phobia or extreme shyness is not uncommon. SSRIs are considered the treatment of choice.

Buspirone, alprazolam, and phenelzine have been shown to be helpful, though they are less well studied and are not considered first-line medications (see Chapter 28.2).

School refusal is associated with both SAD and SP. School refusal occurs in about 1–2% of children and is commonly addressed by pediatricians. Younger children often show reluctance to separate from caregivers with concomitant worries about the caregiver's well-being (SAD), whereas older children demonstrate fear of exposure to unfamiliar or possibly humiliating environments (SP). Somatic complaints, especially abdominal pain and/or headaches, are common. As many as 75% of children who refuse to go to school also suffer from clinical and subclinical depressive symptoms in addition to anxiety. There may be increasing tension in the parent-child relationship or other indices of family disruption (e.g., domestic violence, divorce, or other major stressors) contributing to this disorder. Management of school refusal typically requires parent management or even family therapy. Working with school personnel is almost always indicated; anxious children often require special attention from teachers, counselors, or school nurses. Typically, parents who are coached to calmly send their children to school and to reward the child for each completed day of school will be successful. In cases of ongoing school refusal, referral to a child psychiatrist is indicated. Young children with affective symptoms have a good prognosis, whereas adolescents with more insidious onset or with significant somatic complaints have a more guarded prognosis.

Selective mutism (previously classified as elective mutism) has recently been conceptualized as a disorder that overlaps with social phobia. Children with selective mutism talk almost exclusively at home, though they are reticent to do so in other settings such as school, daycare, or even relatives' homes. Often, one or more stressors—such as a new classroom or parental or sibling conflict—drive an already shy child to become reluctant to speak. Fluoxetine has been shown to be effective for children whose school performance is severely limited by their symptoms (see Chapter 28.2).

Panic disorder is a syndrome of recurrent, discrete episodes of marked fear or discomfort in which individuals experience abrupt onset of physical and psychologic symptoms. The physical symptoms can include palpitations, sweating, shaking, shortness of breath, dizziness, chest pain, and nausea. Children who present with acute respiratory distress, but without fever, wheezing, or stridor also may be experiencing a panic attack. The associated psychologic symptoms include fear of death, impending doom, and loss of control. Panic disorder is uncommon before adolescence, with the peak age of onset being between 15 and 19 yr. Preliminary studies in adults suggest a predisposition to react to autonomic arousal with anxiety is a specific risk factor leading to panic disorder. The increasing rates of panic attack are

also directly related to increasing sexual maturity. Some adolescents with panic disorder may develop **agoraphobia**, a subsequent fear that a panic attack may occur in a place where help or escape may be unavailable. Neither panic disorder nor agoraphobia is well studied in children or adolescents. As in the treatment of adults with panic disorder, SSRIs have shown effectiveness in the treatment of adolescents (see Chapter 28.2).

Children who suffer from *generalized anxiety disorder* (GAD) frequently experience unrealistic worries about future events or about the appropriateness of past behavior and their own competence. They frequently present with somatic complaints, are markedly self-conscious, need large amounts of reassurance, and have trouble relaxing. Onset may be gradual or sudden, though GAD does not often become manifest until puberty. Boys and girls are equally affected and the prevalence in adolescence is 2.4%. GAD is characteristically seen in middle and upper middle class white children. Children with GAD are generally good candidates for cognitive-behavioral therapy, though a trial of buspirone or an SSRI may be indicated when symptoms are particularly limiting.

It is important to distinguish children with GAD from those who present with specific repetitive thoughts that invade consciousness (obsessions) or repetitive rituals or movements that are driven by anxiety (compulsions). The most common obsessions are concerned with bodily wastes and secretions, the fear that something calamitous will happen, or the need for sameness. The most common compulsions are handwashing, continual checking of locks, and touching. In times of stress (bedtime, preparing for school), some children touch certain objects, verbalize certain words, or wash their hands repeatedly. *OCD* is diagnosed when the thoughts or rituals cause distress, consume time, or interfere with occupational or social functioning. The children's Yale-Brown Obsessive-Compulsive Scale (C-YBOCS) and the Anxiety Disorders Interview Schedule for Children (ADIS-C) are reliable and valid methods of discriminating individuals with OCD from those without the disorder. The C-YBOCS is very helpful in following progression of symptoms with treatment. Neuroimaging studies of individuals with obsessive-compulsive disorders have documented abnormalities in the frontal lobes, basal ganglia, and their associated pathways. OCD may present in preschoolers or appear suddenly later in development.

Controlled trials of both pharmacotherapy and cognitive-behavioral therapy have shown efficacy for OCD. All of the SSRIs have established efficacy for the treatment of OCD and fluvoxamine and sertraline have Food and Drug Administration (FDA) approval for use in children. Clomipramine (Anafranil), a tricyclic antidepressant, was the first medication to gain FDA approval for childhood OCD but can cause side effects typically associated with tricyclics, such as dry mouth, dizziness, somnolence, fatigue, and tremor. In addition, tricyclic medications have been associated with electrocardiogram (ECG) abnormalities, and pretreatment and periodic ECGs are necessary. Controlled trials suggest that cognitive-behavior therapy may lead to somewhat higher response rates, greater symptom reduction levels, and more durable treatment gains than medication alone. For this reason, many experts recommend completion of a behavioral treatment with crossover to pharmacologic management when response is partial or symptoms are severe.

Ten per cent of children with OCD seem to have their symptoms triggered or exacerbated by group A ß-hemolytic streptococcal infections (GABHS). In a process similar to Sydenham's chorea, it appears that GABHS bacteria trigger antineuronal antibodies that cross react with caudate neural tissue in genetically susceptible hosts leading to swelling of this region and obsessions and compulsions. This subtype of OCD, called pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS), is characterized by sudden and dramatic onset or

exacerbation of OCD or tic symptoms, associated neurologic findings, and a recent streptococcal infection. The pediatrician should be aware of the infectious cause of some cases of tic disorders and OCD and follow management guidelines (see Chapter 21).

Children with *phobias* avoid specific objects or situations that reliably trigger physiologic arousal (e.g., dogs or spiders). Neither obsessions nor compulsions are associated with the fear response, and phobias only rarely interfere with social, educational, or interpersonal functioning. The parents of phobic children should remain calm in the face of the child's anxiety or panic. Parents who become anxious themselves may reinforce their children's anxiety, and the pediatrician can usefully interrupt this cycle by calmly noting that phobias are not unusual and rarely cause impairment. The prevalence of specific phobias in childhood is 0.5–2.0%. Systematic desensitization is a form of behavior therapy that gradually exposes the individual to the fear-inducing situation or object while simultaneously teaching relaxation techniques for anxiety management. Successful repeated exposure will lead to extinguishing anxiety for that stimulus.

Post-traumatic stress disorder (PTSD) is an anxiety disorder resulting from the long- and short-term effects of trauma that causes behavioral and physiologic sequelae in toddlers, children, and adolescents. A new diagnostic category, *acute stress disorder*, has been added to the nosology, reflecting the fact that traumatic events often cause acute symptoms, which may or may not resolve. Previous trauma exposure, a history of other psychopathology, and parental symptoms of PTSD predict childhood-onset PTSD. Many adolescent and adult psychopathologic conditions such as conduct disorder, depression, and some personality disorders, have been shown to be related to previous trauma. PTSD also is linked to mood disorders, disruptive behavior, and other diagnoses in childhood. Epidemiologic studies have placed the lifetime prevalence of PTSD by age 18 at 6% in a community sample. Many others—up to 40%—may demonstrate symptoms but not fulfill the diagnostic criteria.

Life-threatening events that pose harm to the child or the caregiver and that produce considerable stress or fear are required to make the diagnosis of PTSD. Three clusters of symptoms are also essential for diagnosis: re-experiencing, avoidance, and hyperarousal. Persistent re-experiencing of the stressor through intrusive recollections, nightmares, and reenactment in play are typical responses in children. Persistent avoidance of reminders and numbing of emotional responsiveness such as isolation, amnesia, and avoidance constitute the second cluster of behaviors. Finally, symptoms of hyperarousal, such as hypervigilance, poor concentration, extreme startle responses, agitation, and sleep problems round out the symptom profile of PTSD. Occasionally, children regress in some of their developmental milestones after a traumatic event. Avoidance symptoms are commonly observable in younger children, whereas older children may be more able to describe re-experiencing and hyperarousal symptoms. Repetitive play involving the event, psychosomatic complaints, and nightmares may also be observed.

Initial interventions after a trauma should focus on reunification with a parent and attending to physical needs in a safe place. Aggressive treatment of pain may decrease the likelihood of PTSD, and facilitating a return to comforting routines, including regular sleep, is indicated. Long-term treatment may include individual, group, school-based, or family therapy as well as pharmacotherapy in selected cases. Individual treatment involves transforming the child's concept of victim to survivor and can occur through play therapy, psychodynamic therapy, and cognitive-behavioral therapy modalities. Group work is also helpful for identifying which children may need more intensive assistance. Goals of family work include helping the child establish a sense of security, validating his or her emotions, and

anticipating situations when the child will need more support from the family. Clonidine or guanfacine may be helpful for sleep disturbance, persistent arousal, and exaggerated startle. Co-morbid depression and affective numbing may respond to an SSRI-class of medication, such as sertraline, paroxetine, or nefazodone. Tricyclics may also be effective agents in adolescents, although their efficacy in younger children is questionable (see Chapter 28.2).

Chapter 23 - Mood Disorders

Neil W. Boris
Richard Dalton
Marc A. Forman

Major depressive disorder, dysthymic disorder, and bipolar disorder are the three major types of affective or mood disorders seen in children and adolescents.

23.1 Major Depression

Although in the past there was some doubt as to whether prepubertal children experience depression similar to that seen in adults, this view has been dispelled through the use of structured interviews and rating scales. *Major depression* is characterized by dysphoria (which in children may present as irritability) and an obvious loss of interest and pleasure in usual activities. Diagnostic symptoms also include a significant weight change secondary to decreased or increased food intake, insomnia or hypersomnia, psychomotor agitation or retardation, fatigue or loss of energy on most days, feelings of worthlessness and excessive guilt, diminished ability to concentrate, and recurrent thoughts of death. A melancholic subtype of depression, characterized by marked anhedonia and early morning awakening, has been described in adolescents.

Epidemiology.

The prevalence of depression varies based on sampling and measurement: Studies in childhood report rates of 0.4–2.5% and in adolescence, 0.4–8.3%. The lifetime prevalence of depression starting in adolescence is 15–20%, underscoring the fact that depression is a common disorder. At least twice as many girls as boys meet criteria for depression during adolescence; prepubertal depression is equally common among the sexes. Depression is undertreated across the life span, despite available and effective treatments shown to counter the high cost of lost productivity (e.g., school failure in adolescence) associated with ongoing depression.

Etiology.

Many factors contribute to causing depression. However, there is strong evidence of a genetic basis for major depressive disorders across the life span. Individuals at high genetic risk appear to be more sensitive to the effects of adverse environmental conditions. Twin studies have shown a 76% concordance for depression among monozygotic twins reared together and 67% for monozygotic twins reared apart compared with 19% for dizygotic twins reared together. There is also an increased rate of depression (3–6 times greater) in first-degree relatives of patients suffering from a major affective disorder. Low functional levels of norepinephrine and serotonin are thought to be important genetic markers for depression and low urinary levels of 3-methoxyhydroxyphenylglycol and 5-hydroxyindoleacetic acid have been described in depressed patients. Positron emission tomography scans reveal altered metabolic activity in specific brain regions associated with mood, sleep, and appetite regulation. Neuroimaging data are reinforced by the fact that antidepressants that block presynaptic reuptake of serotonin are highly effective in treating depression. The development of hopelessness and helplessness secondary to an actual loss or the perception of loss suggests that cognitive factors play a role in the onset and maintenance of depression. Numerous studies confirm that adverse life events clearly play a role in causing depression, and there is even research on the pathophysiology linking experience and mood.

Clinical Manifestations.

Depressive symptoms vary according to age and developmental level. Spitz described the *anaclitic depression of infancy,* and Bowlby observed that separation from a primary caregiver after 6–7 mo of age first leads to strong protest (e.g., crying and searching). Eventually, abandoned infants become withdrawn and apathetic, exhibiting hypotonia, lethargy, and an obviously sad facial expression. These infants often cry silently and, when picked up, may cling to a stranger, though they are usually inconsolable.

The clinical picture of depression in children somewhat parallels that of adults, except that children are more likely to present with separation anxiety, phobias, somatic complaints, and behavioral problems. Instead of reporting sadness, children may behave irritably. The hallmark of psychotic depression in children is the occurrence of hallucinations; delusions are more common in adolescents and adults.

The symptoms of a major depressive episode usually develop over a period of many days or weeks. The duration of each episode of depression is variable, though symptoms often persist for 7–9 mo without treatment; 6–10% of episodes are more protracted. Several longitudinal studies show that children and adolescents who are depressed are at risk for the development of later episodes of depression. Other studies have shown that, within 2 yr of the first depressive episode, 40% of children who have had a major depressive disorder experience a relapse. For children, like adults, depression should be considered a chronic disease marked by periods of normal mood. However, 20–40% of teenagers hospitalized with major depression develop a manic episode within 3–4 yr of discharge. Three predictors of later mania in depressed adolescents are (1) a depressive symptom cluster characterized by rapid onset, psychomotor retardation, and mood-congruent psychotic features; (2) a family history of bipolar illness or other affective illness; and (3) induction of hypomania by antidepressant medication. The picture of depression is further complicated by the fact that co-morbidity commonly occurs: 20–50% of depressed children have two or more diagnoses, including an anxiety disorder (30–80%), a disruptive behavior disorder (10–80%), dysthymic disorder (30–80%), or substance

abuse disorder (20–30%).

Diagnosis.

The Children's Depression Inventory, Children's Depression Scale, Depression Self-Rating Scale, and the Center for Epidemiological Studies Depression Scale for Children have all been shown to be helpful to clinicians in diagnosing depression in children and adolescents. However, clinical interview with the child and multiple adults familiar with the child

remains the gold standard. There are no biologic tests specific for depression, though various biologic markers have been studied. For instance, during major depressive episodes, some children have been shown to hyposecrete growth hormone in response to insulin-induced hypoglycemia, whereas others produce higher growth hormone peaks during sleep. However, no test has sufficient sensitivity or specificity to assist in diagnostic assessment.

Treatment.

Both psychotherapy and pharmacotherapy are effective in treating depression in childhood and adolescence. Psychotherapy is especially important for patients with multiple diagnoses or precipitants related to family disruption or conflict. Cognitive behavioral therapy (12–16 wk) has been most well studied and is effective in about 70% of cases of adolescent depression. Rigorous studies have also shown that selective serotonin reuptake inhibitors (SSRIs) reduce depressive symptoms in about 70% of cases. However, only 1 of 12 controlled studies of tricyclic antidepressants (TCAs) have demonstrated efficacy, and these agents, which have a narrow therapeutic window and serious side effects, are rarely indicated for depression in childhood. Furthermore, because depression is strongly associated with suicidal ideation and attempts and TCAs are deadly in overdose, the pediatrician should avoid using these drugs for depression.

23.2 Dysthymic Disorder

When compared with major depression, *dysthymic disorder* is a less severe but more protracted syndrome involving depressed mood for at least 1 yr. Poor appetite, sleep problems, decreased energy and self-esteem, and feelings of hopelessness are characteristic of dysthymia. Dysphoria is less intense but more chronic, with only brief periods of normal mood.

Etiology.

Although the genetic basis of major depression has been demonstrated, the data regarding the genetic basis for dysthymic disorder are less firm. Dysthymia may be a partial phenotypic expression of an underlying genetic disorder or a different syndrome that has certain symptom clusters in common with major depression. Prevalence in childhood is 0.6–1.7% and in adolescence, 1.6–8.0%.

Clinical Manifestations.

With the exception of hallucinations and delusions, other symptoms of major depression may be present, though severe sleep disturbance, appetite loss, or anhedonia suggest evolving major depression. Children who have dysthymia have had frequent disruptions of important relationships, often beginning as early as infancy. There is often a history of depressive illness in both parents. Affected children show more general emotional and social maladjustment. They often present as helpless, passive, clinging, dependent, and lonely children. Others relate in a more hardened, aloof, negativistic manner and are reluctant to invest emotion or trust in relationships. Untreated dysthymic disorder is generally chronic and is associated with increased risk for the subsequent development of major depression (70%), bipolar disorder (13%), and substance abuse disorder (15%). Frequently, children with dysthymia have a co-occurring second psychiatric disorder.

Treatment.

Antidepressant pharmacotherapy is useful in the treatment of dysthymic patients, though there are few good studies of dysthymia in children. Antidepressants are especially helpful for those who display vegetative symptoms of depression. When dysthymic symptoms are associated with a second condition (anorexia, somatization disorder, substance abuse disorder, physical illness), both conditions require intervention. Often a full spectrum of therapies, including alliance building and dynamic psychotherapy, family therapy, parent management training, liaison work with the child's school, and pharmacotherapy, is indicated.

23.3 Bipolar Disorder

Bipolar illness is characterized by either alternating depression and mania (a typical adult presentation) or rapid cycling of mood, which may appear as irritable depression and dysregulation of affect. The rapid cycling, mixed variant is more common in children and young adolescents. One per cent of adult bipolar patients report that their symptoms began in early childhood; about 10% report that symptoms began during early adolescence. Epidemiologic studies suggest that the prevalence rate during childhood and adolescence is 1%, though differing diagnostic standards have led to varying estimates of prevalence.

Etiology.

Bipolar disorder has genetic roots: a concordance rate of 65% in monozygotic twins and less than 20% in dizygotic twins supports this hypothesis. Further, first-degree relatives of individuals with bipolar disorder are much more likely than the general population to develop a mood disorder. Twenty per cent of adolescents presenting with major depressive symptoms develop manic episodes later.

Clinical Manifestations.

The clinical manifestations of bipolar disorder may be different for prepubertal children and early adolescents as compared with older adolescents and adults. Defined episodes of depression alternating with euphoria, grandiose thoughts, high activity levels, pressured speech, distractibility, hypersexuality, hyper-religiosity, overspending, and hallucinations and delusions are characteristic of classic bipolar disorder and represent the typical mid to late adolescent or adult pattern of symptoms. In 70% of these cases, careful history reveals that at least one episode of depression preceded the manic symptoms. Some children and adolescents, however, present with irritability, grandiosity, explosive aggression, hyperactivity, rapid thinking, and cognitive impairment. These children, who often do not fully meet current DSM-IV criteria for bipolar disorder, clearly suffer from symptoms that impair their functioning and require intervention. Rarely, symptoms are evident as early as the preschool period. Because some studies suggest that children with early-onset symptoms are more likely to have first-degree relatives with a mood disorder, they are currently considered by many psychiatrists as suffering from a form of bipolar disorder. These children may fulfill criteria for one or more disruptive behavioral disorders, particularly attention-deficit/hyperactivity disorder and/or conduct disorder. There is considerable controversy about the prevalence and diagnostic features of this early-onset form of bipolar disorder. However, severe early mood instability is associated with high levels of school failure, poor peer relations, and high levels of

risk taking and substance abuse in early adolescence.

Treatment.

Therapy of bipolar disorder typically requires the use of mood-stabilizing medications (Chapter 28.2). Psychotherapy alone is usually ineffective for bipolar disorder. The pharmacologic management of bipolar disorder is generally best left to child psychiatrists except in unusual circumstances. Lithium carbonate is effective in the treatment of bipolar illness and manic symptoms in about 60% of cases. Lithium is administered orally, followed by measurement of blood levels. The ideal therapeutic range for the initial treatment of acute symptoms is a blood level of 1.0–1.2?mEq/L, and the recommended blood level for maintenance therapy is 0.5–0.8?mEq/L. Lithium is associated with renal impairment and hypothyroidism, and baseline and follow-up renal function and thyroid function tests are imperative. Lithium side effects are the major reason that this medicine is not always useful for maintenance purposes. The antiepileptics, carbamazepine (Tegretol) and valproic acid, are especially effective in rapid cycling adult bipolar disorder. These agents are also now considered first-line agents for bipolar disorder in childhood. Both are potentially toxic to the liver, and baseline and follow-up liver function tests are imperative. Tegretol is also associated with Stevens-Johnson syndrome and leukopenia,

though both are rare events. Several new mood-stabilizing agents are also used for bipolar disorder. Lamotrigine is the most promising of these, especially for depression associated with bipolar disorder. However, about 10% of children and adolescents taking lamotrigine develop a rash; because a high percentage of these rashes evolve into Stevens-Johnson syndrome and other life-threatening rashes, the medicine should be discontinued when the rash is first noted. In addition to mood stabilizers, novel antipsychotic medications, especially risperidone and olanzapine, have shown promise. They are especially useful with children from chaotic families who cannot be counted on to comply with difficult dosing requirements and frequent lab visits.

Early onset of symptoms and high levels of aggression appear to be related to treatment failure. Some children require multiple medications. Family conflict is commonly associated with early-onset bipolar disorder, and one of the psychotherapeutic approaches helpful in conduct disorders is typically indicated (see Chapter 28).

Chapter 24 - Suicide and Attempted Suicide

Neil W. Boris
Richard Dalton

See also Chapter 102 .

Suicide is the second leading cause of adolescent death, and the rate of completed suicide for males has increased dramatically in the last 4 decades. The vast majority of children and adolescents who complete suicide have some form of psychiatric illness. Pediatricians and primary care providers should ask about suicidal ideation at each adolescent visit and must be comfortable assessing suicide risk and knowing when to refer children and adolescents for mental health care.

Epidemiology.

Suicide is extremely rare before puberty. However, rates of completed suicide increase steadily across the teen years and into young adulthood, peaking in the early 20s. Yearly in the United States, about 2,000 13- to 19-yr-olds complete suicide, though underreporting of suicide has been documented. As age increases from prepuberty to late adolescence, the ratio of male to female suicides rises from 3:1 to about 4.5:1. It is estimated that there are 5 to 45 suicide attempts for each completed suicide and in some samples as many as 25% of adolescents admit to suicidal ideation. About 3 times as many females attempt suicide as males. Most suicide attempts among females involve ingestion or superficial cutting, whereas more lethal means are used by males (e.g., hanging, firearms). The increase in suicide rates has been greater in black than in white youth resulting in the rate of suicide among black teens approaching that of whites, especially in late adolescence; as is true for whites, 3–5 times as many black males complete suicide as females.

RISK FACTORS.

Perhaps the easiest way to understand the origins of suicidal behavior is by considering a biopsychosocial framework. From the biologic perspective, twin studies that control for life events known to be related to suicidal behavior reveal that suicidal ideation and suicide attempts are significantly more common among monozygotic twin pairs than dizygotic twin pairs. Pedigree analyses further support the influence of genetic factors on suicidal behavior. In addition, a large body of recent research focused on understanding what the genes associated with suicidal behavior might code for suggests that heritable alterations in the serotonin system are associated with suicide completion. The serotonin system is important in regulating impulsivity, aggression, and mood, and these three factors are, in turn, related both to psychiatric diagnoses and to gender. For instance, although adolescent females are more at risk for depression than males, males are generally more aggressive and impulsive than females. There is a strong association between mood disorders and both suicide attempts and completion for both sexes. For males, the addition of conduct disorder or chronic anxiety is also associated with completed suicide, especially when combined with alcohol abuse (which is associated with impulsivity). For females, chronic anxiety, especially panic disorder, is associated with suicide completion. Not surprisingly, children and adolescents with a previous history of suicide attempts are at higher risk for suicide completion regardless of their psychiatric status. These data suggest that there are several interconnected risks, probably mediated primarily by biologic and genetic factors, which predict suicide.

Psychologic and social factors must also be considered to obtain a more complete picture of suicidal behavior. Two thirds of child or adolescent suicide attempters can name a precipitating event for their action. For instance, a remote or recent history of child maltreatment or sexual assault is associated with suicide. Many studies have revealed a more general association between family conflict and suicide attempts, and this association is strongest for children and early adolescents. For older adolescents, life events such as relationship breakups are commonly associated with suicide attempts. Adolescents who identify themselves as homosexual are at increased risk for suicide, and those with gender dysphoria appear also to be at high risk for suicide. When a feeling of hopelessness is associated with an adolescent's current psychologic state, then suicide risk increases. For some recent immigrants, for instance, high levels of acculturative stress, especially in the context of family dysfunction and the perception of limited options in the future, are associated with suicidal ideation.

A major factor predicting death from suicide is lethality of means used by the suicidal child or adolescent. So-called “violent” suicides, those completed by use of firearms or hanging, account for the increased suicide rate among adolescent males. Use of carbon monoxide poisoning in adolescent suicide is uncommon but deadly. Overdoses, on the other hand, are common but do not often kill. Preadolescents attempt suicide most commonly by jumping from heights; self-poisoning, hanging, stabbing, and running into traffic are less common. Still, episodes of self-poisoning that occur after age 6 yr are less likely to be accidental and should be treated as if the behavior had suicidal potential or as a possible case of child abuse and neglect.

Assessment and Management.

Assessment of suicidal ideation should be a part of each health visit in adolescence (see Chapter 100). There is no evidence that discussing suicide with individuals increases their likelihood of harming themselves. On the other hand, there is evidence that suicidal persons who seek medical care do not discuss suicidal thoughts, symptoms of depression, or patterns of drug use unless specifically asked. Given that suicide is a leading cause of death in adolescence, the physician will

prevent more deaths by asking about suicide than by auscultating the lungs.

The first principle of suicide assessment is that suicidal ideation should be taken seriously. Physicians, parents, and others must scrupulously avoid sarcasm, kidding, daring, or belittling the individual who reveals thoughts of suicide. If a suicidal threat is labeled “manipulative,” power or control becomes a major issue influencing behavior, and the risk of suicide may increase. In the case of the child or adolescent seen after a suicide attempt, a thorough history regarding ingestion is necessary, and aggressive management for poisoning implemented as indicated. Alcohol or drug intoxication is not uncommon and may also require acute management.

The second principle of suicide assessment is that the child or adolescent must be understood within the biopsychosocial framework. Box 24–1 (Box Not Available) lists some guidelines for assessment. The child or adolescent's psychiatric status is a primary concern. A careful psychiatric history and mental status examination are necessary to assess risk for suicide completion. Physicians who are uncomfortable with psychiatric assessment should seek

Box 24-1. Checklists for Assessing Child or Adolescent Suicide Attempters in an Emergency Room or Crisis Center

(Not Available)

From American Foundation for Suicide Prevention: Today's suicide attempter could be tomorrow's suicide (poster). New York, American Foundation for Suicide Prevention, 1999, 1-888-333-AFSP.

immediate consultation with a mental health professional. Signs and symptoms of mood disorders, conduct problems, chronic anxiety, or substance abuse suggest the need for intervention and indicate risk for eventual suicide completion. Previous suicide attempts should also be documented. In order to identify precipitating events, the physician should carefully explore, in detail, the child's life during the 48–72?hr prior to either the threat or the suicide attempt. The degree of premeditation or impulsivity should be assessed. In most instances, a child or an adolescent will openly discuss how intent they were on harming themselves, their reasons for attempting suicide, and whether they remain suicidal. Furthermore, the physician should be able both to evaluate the response of the immediate family to a child or adolescent's attempt and to assess the degree of ongoing family conflict.

When suicidal patients have been seen in the physician's office, the physician should enter into a no-suicide contract with the patient. The parents should be notified, and a psychiatric consultation should be obtained. Because 50% of suicide attempters do not attend even one outpatient psychiatric session, the physician should procure a specifically arranged appointment within 1 or 2 days. If possible, the patient and family should meet the therapist immediately after the examination by the physician. In most cases, suicide attempters who are seen in the emergency room should be admitted to the hospital for 1 day or more so that a more adequate evaluation can be made of the patient's frame of mind and of the circumstances of the family or environment. Such admissions usually require 2–3 days, unless medical needs require a longer stay or a serious psychiatric disorder, such as depression or psychosis, is found. If social service and psychiatric assessments are adequate and arrangements for appropriate follow-up care can be made, disposition can be made fairly rapidly. The physician must give careful attention to how the family and friends have responded to the patient's act. A hostile and angry family, such as is frequently seen, will necessitate a different disposition or resolution than a family that is supportive, sympathetic, and understanding. The latter supports a decision for the patient to return home. Some families may completely deny the seriousness of the behavior; this can be discouraging and provocative to the patient, whose act has been a desperate attempt to compel a different response. The family members should be helped to examine their roles in the interactions that preceded the attempt, without being made to feel overly guilty.

Psychiatric hospitalization is indicated when the individual continues to be actively suicidal, when major psychiatric disorders are found within the attempter, or when major family problems complicate ongoing protection of the attempter.

Chapter 25 - Disruptive Behavioral Disorders

Neil W. Boris
Richard Dalton

Numerous behaviors considered appropriate at certain early developmental levels are obviously pathologic when they present at later ages. Lying, impulsiveness, breath holding, defiance, and temper tantrums are frequently noted around the ages of 2–4 yr, when children begin to need autonomy but do not have the motor and social skills necessary for successful independence. These behaviors are typically the result of frustration and anger. About one half of preschoolers in the United States are brought to the attention of physicians at some time because of destructive and disobedient behaviors. Moreover, some studies suggest that disruptive, antisocial behaviors are intermittently committed by one half of this country's adolescents.

Breath holding is not unusual during the first years of life. Breath holding is frequently used by infants and toddlers in an attempt to control their environment and their caregivers. Although some children hold their breath until they lose consciousness, sometimes leading to a seizure, there is no increased risk of their later developing a seizure disorder. Parents are best advised to ignore the behavior. Without sufficient reinforcement, breath holding most often disappears. When breath holding does not respond to parent coaching or is accompanied by head banging or high levels of aggression, referral for developmental evaluation or family counseling is indicated.

Defiance, oppositionalism, and *temper tantrums* are not uncommon in children 18 mo to 3 yr of age, when the struggle to develop a goal-corrected partnership with primary caregivers is paramount. Parental and caregiver response to this behavior is very important. Caregivers who respond to toddler defiance with punitive anger run the risk of reinforcing the defiance and teaching the child that out-of-control emotions are a reasonable response to frustration. In response to tantrums and oppositionalism, parents are advised to give the child time and space to recover by turning away briefly. It is useful to advise parents to tell their child, once he or she is calm, that the reasons for frustration are understandable but that oppositional behavior is not acceptable. If the child presents with escalating oppositionalism, parents should be advised to calmly place the child in time-out for 2–3 minutes (see

Chapter 5).

If behavioral measures such as time-out fail, physicians must assess how the parents handle anger before making further recommendations about how to approach the child's problems. Children are often frightened by the strength and intensity of their own angry feelings and by the intensity of the angry feelings they arouse in their parents. It is therefore of prime importance that parents model the anger control that they wish their children to exhibit. Some parents are unable to see that they sometimes lose control themselves; they are not, therefore, helping their children to internalize controls. Advising parents to calmly provide simple choices of activities that a toddler or young child may choose will help the child to feel more in control and to develop a sense of autonomy. Providing the child with options also typically helps reduce the child's feelings of anger and shame. Such negative, internalized feelings may later have adverse effects on interpersonal relationships, intimacy, and personality development.

Lying is often used by 2–4 yr olds as a method of playing with the language. By observing the reactions of parents and caregivers, preschoolers learn about expectations for honesty in communication. Lying is also a form of fantasy for children, who describe things as they wish them to be rather than as they are. For instance, in order to avoid an unpleasant confrontation, a child who has not done something that a parent wanted may say that it has been done to avoid an unpleasant confrontation. The child's sense of time and reason does not permit the realization that this only postpones an even angrier confrontation.

In school-aged children, lying most often is an effort to cover up something that the child does not want to accept in his or her own behavior. The lie is invented, therefore, to achieve temporary good feeling and protect against a loss of self-esteem. Although lying is common in childhood, children with low self-esteem are more prone to habitually lie. In many cases, habitual lying is also promoted by poor adult modeling. For instance, when mothers and fathers accuse each other frequently of lying, the child, drawn into a loyalty conflict, is likely to become distressed and increase defensive lying. Many adolescents lie to avoid parental disapproval. As with other antisocial behaviors, lying may be used as a method of rebellion.

Regardless of age or developmental level, when lying becomes a frequent way of managing conflict and anxiety, intervention is warranted. Initially, the parents should confront the child to give a clear message of what is acceptable. At the same time, sensitivity and support are necessary for a successful intervention, because children and adolescents may react to their shame and embarrassment with angry denial and acting out. If the situation cannot be resolved (i.e., parental understanding of the situation and the child's understanding that lying is not a reasonable alternative), professional intervention is indicated. In some cases, chronic lying occurs in combination with several other antisocial behaviors and is a sign of an underlying psychopathology or family dysfunction.

Almost all children *steal* something at some point in their lives. When preschoolers and school-aged children steal more than once or twice, the behavior may be a response to a sense of internal loss. These children frequently feel neglected and are, in fact, emotionally deprived. Their stealing is impulsive, but the gratification derived does not satisfy the underlying need. In children and adolescents, stealing can sometimes be an expression of anger or revenge for real or imagined frustrations by the parents. In many instances, stealing becomes one way in which the child or adolescent can manipulate and attempt to control interactions with parents. Like lying, stealing can be learned from adults. Parents who boast about outwitting tax laws or exceeding speed limits are implicitly condoning rule breaking as an acceptable behavior.

It is important for parents to help the child undo the theft by returning the stolen articles or by rendering their equivalent either in money that the child can earn or in services. When stealing is part of a pattern of conduct problems, referral to a child psychiatrist is warranted. Both problematic peer influence and lack of supervision by parents may exacerbate stealing and other conduct problems. Interventions as simple as getting a child a Big Brother or Sister have been shown to improve school function and diminish conduct problems. In some cases, however, more intensive intervention may be necessary.

Unlike the previous behaviors, *truancy* and *run-away behavior* are never developmentally appropriate. About half of school refusal incidents result from child and adolescent behavioral problems; the other half is related to mood and anxiety symptoms. Often, truancy represents disorganization within the home or developing personality problems, or both. Whereas younger children often threaten to run away out of frustration or a desire to get back at parents, children who run away with nowhere to go are almost always expressing a serious underlying problem (see Chapter 39). During middle childhood, most runaways are escaping abuse and neglect within the home. In adolescence, disagreements with the parents, developing personality problems, and abuse and neglect all must be considered as possible precipitants. Adolescent runaways are at extremely high risk for substance abuse, intimate partner violence, and other risk-taking behaviors.

Although the interest in fire is ubiquitous in early childhood, unsupervised *fire setting* is always inappropriate. Early school-aged children tend to set fires because of both curiosity and latent hostility secondary to deprivation within a disorganized and neglectful family. These young children set fires by themselves within their homes. In adolescence, fire setting is a sign of delinquency; again, traumatic experiences, often associated with family conflict, are common. Teenagers often set fires in small groups, seeking revenge upon school and community authorities.

At the very least, fire setting requires intervention by the parents. Most often, intervention by mental health professionals is also indicated. A combination of family therapy, alliance-building individual therapy, parent management training, and community involvement is often necessary to effect a reasonable change. The recidivistic young fire setter is very difficult to manage, however. Many adult arsonists were childhood fire setters.

Although there is no totally satisfactory theory about the nature and cause of *antisocial behavior,* risk factors within the individual and family have been identified. Adoption and twin studies strongly suggest that both genetic factors and child-rearing practices contribute to the development of aggressive behaviors. In well-controlled

studies, adopted children with antisocial biologic fathers presented later in life with more antisocial behaviors than did those with antisocial adoptive fathers. However, children with both biologic and adoptive antisocial fathers were the most antisocial in later life. Sociocultural factors, temperament, some psychiatric conditions, and cognitive limitations can also predispose individuals to antisocial acting out.

Aggression is a serious symptom and is associated with significant morbidity and mortality in childhood. Data suggest that aggression is often stable over time. Children may not “grow out” of this behavior, and early intervention is indicated for persistent aggressive behavior. Aggressive tendencies are heritable, although environmental factors may promote aggression in susceptible children. Both enduring and temporary risk conditions impacting a family may increase aggressive behavior in children. For instance, aggression in childhood has been correlated with family unemployment, discord, criminality, and psychiatric disorders as well as births to teenage or unmarried mothers. Boys are almost universally reported to be more aggressive than girls. In many animals, administration of male sex hormones to females produces more aggressive behavior. Difficult temperament and later aggressiveness have been shown to be related, though there is evidence that these children may elicit punitive caregiving within the family environment, setting up a cycle of increasing aggression. Aggressive children often misperceive social cues and react with inappropriate hostility toward both peers and parents. Nonetheless, marital discord and aggression within the home certainly contribute to aggression by children.

Clinically, it is important to differentiate the causes and motives for childhood aggression. Intentional aggression may be primarily instrumental, to achieve an end, or primarily hostile, to inflict physical or psychologic pain. Children who are callous and unempathic and who are frequently aggressive require mental health intervention. These children are at high risk for suspension from school and eventual school failure. Learning disorders are commonly evident and should be screened for in aggressive children. Other forms of psychopathology are not uncommon; in particular, aggressive children with attention-deficit/hyperactivity disorder (ADHD) may develop oppositional-defiant disorder and/or conduct disorder. Some aggressive, impulsive children may instead have bipolar disorder; a family history of mood disorders, grandiosity, and cyclic mood disturbance may be evident in the history of these children.

Aggressive behavior in boys is relatively consistent from the preschool period through adolescence; a boy with a high level of aggressive behavior from 3–6 yr of age has a high probability of carrying this behavior into adolescence, especially without effective family-focused intervention. The developmental progression of aggression among girls is less well studied. There are clearly fewer girls with physically aggressive behavior in early childhood. On the other hand, interpersonal coercive behavior, especially in peer relationships, is not uncommon among girls and appears to be related to the development of more physical aggression in adolescence (e.g., fighting, stealing, etc.).

Children exposed to aggressive models on television or in play display more aggressive behavior compared with children not exposed to these models (see Chapter 34). Parents' anger and aggressive or harsh punishment model behavior that children may imitate when they are physically or psychologically hurt. As Lewis has noted, parental abuse may be transmitted to the next generation by several modes: Children imitate aggression that they have witnessed; abuse can cause brain injury (which itself predisposes the child toward violence); and internalized rage more often than not results from abuse.

Conduct disorder is a distinct clinical entity manifested by several different antisocial behaviors: stealing, lying, fire setting, truancy, property destruction, cruelty to animals, rape, use of a weapon while fighting, armed robbery, physical cruelty to others, and repeated attempts to run away from home. A pattern of such behaviors that has existed for at least 6 mo warrants the diagnosis of conduct disorder. One third to one half of adolescent psychiatric clinic patients present with symptoms of conduct disorder. *Oppositional-defiant disorder* is defined by less severe behavior than conduct disorder: temper tantrums, continuous arguing, defiance of rules, continual blaming of others, angry and resentful affect, spiteful and vindictive behavior, and frequent use of obscene language. Some children may present with symptoms of all three disruptive behavior disorders (ADHD, oppositional-defiant disorder, and conduct disorder). For instance, one third of children and adolescents with psychiatric diagnoses seen in community-based clinics are considered oppositional, and children with ADHD are significantly more likely to meet criteria for oppositional-defiant disorder than those with other presenting problems. Still, the majority of children diagnosed with a disruptive behavior disorder meet criteria only for that disorder. The risk factors (from child, parent, and environment) associated with the development of conduct disorder are very similar to those previously mentioned in association with the development of specific antisocial and aggressive behaviors. Aggressive behavior is stable across generations within families. Inconsistent parenting practices as well as overly punitive disciplinary measures have been associated with conduct-disordered children. Parents of conduct-disordered children are less accepting of their children and show less warmth and support for them. However, only about a third of children with conduct disorder go on to have antisocial personality disorder in adulthood. Adult criminality is predicted by an early age of onset of conduct disorder symptoms, numerous episodes and varieties of antisocial behaviors, parental criminality, and marital discord.

In many children, oppositional behavior may appear in the form of *passive-aggressive behaviors*. Prevalence rates of 16–22% have been noted. Children with passive-aggressive behavior express hostility indirectly as procrastination, stubbornness, or resistance. Parents often complain that such children do not hear them and that they fail to respond to repeated requests. Academic underachievement is common. Children may unconsciously adopt passive-aggressive strategies for a variety of motives: to gain independence while maintaining dependence; to counter underlying low self-esteem; to maintain control and autonomy when threatened by anxiety; and to get revenge. These children are fearful of direct expression of assertiveness, aggression, and hostility. The child-rearing styles of their parents are often intimidating, critical, and inconsistent or, on the other hand, indulgent and permissive.

Treatment.

Many different approaches have been used in the therapy of children and

adolescents with aggressive behavior, conduct disorder, and oppositional-defiant disorder. Individual treatment focusing on alliance building and conflict resolution is sometimes useful in establishing the basic trust necessary for a positive therapeutic outcome; however, individual therapy is not always effective in ameliorating behavioral problems. Group therapy has shown some promise in treating adolescents with behavioral difficulties, and anger management therapy has demonstrated some positive results with younger children. Training in problem-solving skills involves modeling, role playing, and practicing to help children deal more successfully with interpersonal relations; it is somewhat effective in modifying maladaptive styles of relating and behaving. Effective results have been obtained with parent management training, in which parents are trained directly to promote prosocial behaviors within the home and to place reasonable limits on unwanted, destructive behaviors. In the case of passive-aggressive behavior, for instance, parents would be encouraged to set firm limits and expectations for the child and reach agreement with the child on what his or her important tasks and responsibilities are. Compliance and age-appropriate assertiveness and independence are then promoted and rewarded. Multisystemic therapy (MST), an in-home treatment involving the identified patient, parents, siblings, and peers as well as school and neighborhood and other environmental forces, has been shown to be effective with aggressive, conduct-disordered children and adolescents. This multilevel approach is informed by data on the varying ecologic risks that are related to conduct disorder.

Pharmacotherapy for aggression or disruptive and antisocial behavior is generally used as an adjunct to family-based therapy, parent training, or MST. There are little data suggesting that pharmacotherapy alone is effective in reducing persistent aggression, oppositional behavior, or antisocial behavior. However, children with underlying biologic vulnerability (intermittent psychotic disorders, attention deficit disorder) may benefit from judicious use of appropriate medication. There are no medications specifically intended for treatment of antisocial behaviors. Lithium, antipsychotics, anticonvulsants such as valproate, and a_2 -agonists such as clonidine may diminish aggressive acting out in selected individuals, though these medications may also have significant side effects (see Chapter 28.2). Some children present with such severe behavioral problems that residential treatment or psychiatric hospitalization is necessary for a successful outcome.

Chapter 26 - Sexual Behavior and Its Variations

Richard Dalton

See also Chapters 555 and 556 .

Gender identity refers to the individual's sense of self as a male or a female. *Gender role* refers to those behaviors within a culture commonly thought to be associated with maleness or femaleness. Thus, one's gender identity is intact when a biologic male identifies himself as a man and a biologic female identifies herself as a woman. If the male performs the sort of behavior associated with being a man within his culture, he is said to fit comfortably within his gender role. However, if a man is uncomfortable with those behaviors identified with men within his culture, the implication is that he has trouble with his gender role. The same is true for women. However, as society has changed, gender roles have changed. In the past, gender roles were shaped by traditionally defined masculine and feminine roles. As the economics of family life have changed—and both sexes have become potentially self-sufficient economically—gender roles, as they relate to job choices and performance, have changed dramatically or, in some cases, have simply disappeared. Fewer behaviors are specific solely to one gender.

Children identify themselves as boys or girls by about 18 mo of age (i.e., establish a gender identity). Between 18 and 30 mo of age, children establish *gender stability,* the concept that boys become men and girls become women. By 30 mo, gender constancy, the immutability of one's gender, is firmly established and resistant to change. Although there are numerous theories suggesting which environmental and biologic factors are most important to the establishment of a firm gender identity, at this point we still do not understand, in a way that has treatment implications, which factors are most important in any given child.

Children are naturally curious about their bodies. The 2-yr-old child ought to be taught the proper names for the parts of the body, including the genitals. Parents should react calmly when their children explore and manipulate their own bodies with enjoyment, although open masturbation by older children suggests poor awareness of social reality or lack of parental censorship. Parents should inform their children that *masturbation* is not a social activity and should be limited to the bedroom when the child is alone. An overly excited or overly punitive reaction will serve only to excite the child. It is important that masturbation be accepted as a normal aspect of the child's sexual life and that guilt be avoided. By puberty, children should be given explanations of its normality. This can be done in conjunction with explanations of ejaculation, orgasm, and menstruation so that children can understand them, too, as normal bodily functions.

It is quite common for preschool children to hug and kiss each other. More explicit sexual behavior, such as oral contact, attempts at simulated intercourse, or anal stimulation, is probably learned through observation or direct involvement with older children or adults. Intervention designed to uncover the source of the child's knowledge followed by appropriate action is indicated in these situations (Chapter 35).

Especially between the ages of 10 and 12 yr, boys and girls typically explore sexual issues with best friends (same-sex friends) as a means of gathering information. This should not be viewed as a prelude for homosexuality but as a developmental stage in most children. At any age, the compulsive need for sex serves as a defense against underlying dependency, separation, and autonomy issues. It is usually during adolescence that gender object interests are realized. The teenager's actual or

perceived sexual experiences and their reinforcements are important in shaping ultimate gender role behaviors.

Transsexualism, the conviction by a person biologically of one gender that he or she is a member of the other gender, is the most obvious example of gender identity confusion. Transsexual adolescents feel discomfort and a sense of inappropriateness about their assigned sex. They spend years trying to figure out how to get rid of the primary and secondary sexual characteristics that define them biologically. Gender roles of the opposite biologic sex are usually adopted.

The prevalence of transsexualism is 1/30,000 for males and 1/100,000 for females. Transsexuals usually have a difficult time with social and occupational functioning. Concurrent psychopathologic conditions and depression are part of the reason; societal consternation is the other part. The natural history of transsexualism is not well understood. A preponderance of adult transsexuals had gender identity disorders as children and adolescents. Extreme femininity in boys is a predisposing factor. Some say that they remember being confused about gender identity as early as 2 yr of age. Which particular effeminate boys will later show transsexual behavior cannot be accurately predicted.

Treatment of transsexualism has taken two directions. Many transsexual adults have opted for hormonal and surgical therapies to produce primary and secondary sexual characteristics of the gender with which they identify. Follow-up studies consistently show continued distress after these treatments. Long-term dynamic and behavioral therapies also have been tried. Although there are anecdotal reports of successful re-identification with the given biologic sex, without statistical controls it is impossible to know whether this represents a response to therapy or a spontaneous change that would have occurred without it. Spontaneous remissions occur.

Transvestism, cross-dressing, may occur transiently in preschool boys who dress up

in their mothers' clothing, or it may occur chronically in preschool and school-aged boys who feel genuinely excited when dressed in women's clothing. Cross-dressing in girls is rarely an identified problem. Chronic cross-dressing might represent underlying transsexualism, although that is generally not the case. Transvestism usually indicates that other gender roles may also be problematic for the individual. Physicians consulted by parents should investigate other areas of gender identification and gender behavior. Does the child verbalize a preference to be of the opposite sex? Does the child deny or disparage his or her own sexual anatomy or assert that opposite anatomic structures will develop? Three to 6% of school-aged boys and 10–12% of school-aged girls often behave like the opposite sex, but less than 2% of boys and 2–4% of girls actually wish to be the opposite sex.

26.1 Gender Identity Disorder

Ten or more gender-atypical behaviors (GABs) are exhibited in 22.8% of school-aged boys and 38.6% of girls. Most children exhibit one or more GABs. These behaviors are to be expected in most children and are most often not indicative of gender identity disorder (GID). However, persistent distress about being a particular gender while being preoccupied with cross-gender roles or repudiation of given anatomic genital structures is the hallmark of GID. It encompasses transsexualism, transvestism, and effeminacy in boys. The cause of GID is unknown. Some suggest that GID ought not be considered a psychiatric disturbance. Despite the fact that normative studies consistently show that more girls express the wish to be the opposite sex, clinic samples consistently include many more boys than girls (7 to 1).

Clinical Manifestations.

Many GID children develop the disorder prior to 4 yr of age. They are often ostracized by peers and have a difficult social adjustment, sometimes with subsequent depression. One half or more of the boys develop a homosexual orientation during adolescence and adulthood. GID is associated with numerous other childhood and adolescent disorders. Using the Child Behavior Checklist, it has been shown that 84% of feminine boys display behavioral disturbances similar to those seen within a psychiatric clinic population; 60% endorsed items related to peer difficulties and met the criteria for the diagnosis of separation anxiety disorder. Others have found that GID is unrelated to ethnic background, religion, or educational level. Although the natural history of GID suggests a strong relationship between GID and homosexuality, the fact that many gay men and lesbians do not retrospectively recall a history of cross-gender behavior and that a proportion of individuals with childhood GID (10–30%) later identify as heterosexual indicate that GID is probably not just an early manifestation of homosexuality.

Treatment.

The relationship between GID and separation anxiety disorder and other disturbances supports the importance of psychotherapy and possibly pharmacotherapy if behaviors satisfy criteria for separation anxiety disorder or other anxiety disorders. Other approaches are often employed and have been shown to be helpful. Parenting techniques that specify which behaviors are appropriate and what is expected of the child regarding gender role behaviors have shown promise in managing a significant percentage of children with GID. The extent of parental involvement in treatment appears to be correlated with a lessening of cross-gender behaviors. The physician needs to help the parents control their own frustration and disappointment and minimize judgmental, rejecting behavior. Punishment, castigation, or shaming will not support the child's attempts to struggle with whatever intrapsychic, interpersonal, or cultural conflicts exist. Underlying family conflicts and parent-child conflicts need to be managed therapeutically.

26.2 Homosexuality

Homosexuality, the romantic and physical attraction to someone of the same gender, has occurred throughout the ages in about 5% of men and women. Historically, acceptance of homosexuality has waxed and waned within societies. The view is currently held by some that homosexuality is best regarded as an alternative lifestyle. The American Psychiatric Association no longer lists it among mental disorders.

Etiology.

This is uncertain. Many view its development as a normal variant of sexual development; others point to problematic parent-child relationships. Numerous psychologic theories have been proffered to explain homosexual development. They include problems of sexual identification with parents; problematic relationships between either parent and the child; abuse; overly eroticized attachment; and underlying anxiety and affective proclivities in the individual who will later present with homosexual behavior. Although each theory has been accompanied by anecdotal reports and case studies, none has been substantiated in well-controlled studies.

Biologic causes have also been proposed. Focusing on the perceived homology between homosexual behavior in humans and lower animals, researchers have proposed the “dual mating center” theory, stating that there are hypothalamic areas that regulate male and female sexual behavior. It is hypothesized that too little androgen production in males during a critical prenatal period causes the female center to overdevelop; conversely, excessive androgen production in females leads to the overdevelopment of the male center. Proponents point to the fact that some homosexual men demonstrate “estrogen feedback responses,” in which, because of decreased androgen levels, administration of estrogen causes increased production of luteinizing hormone. Many other investigators dispute this

theory because of the lack of consistent findings (e.g., XY males with testicular feminization syndrome do not exhibit this response).

LeVay's finding that heterosexual and homosexual men have differences in hypothalamic structure and size also suggests a biologic substrate for sexual orientation, although the possibility of AIDS in his postmortem specimens may have biased these findings. Other researchers have noted that the anterior commissure in homosexual men is significantly larger than that in heterosexual men. This anatomic difference correlates with both sexual orientation and gender; i.e., the anterior commissure is also larger in heterosexual women than in heterosexual men. Furthermore, Hamer et al. discovered a possible genetic marker for male homosexuality in a small group of individuals and are searching for a gene. Many researchers are skeptical of these biologic findings. Some note that the current evidence that postulates biologic factors in the development of sexual orientation is no more compelling than the current evidence linked to psychologic theories.

There are probably multiple mechanisms leading to homosexuality in adolescence and adulthood, just as there are probably multiple mechanisms leading to heterosexuality; many complex factors contribute to sexual development. Cultural, biologic, and psychologic factors probably contribute to sexual orientation development.

Clinical Manifestations and Diagnosis.

If a child is found to be engaging in homosexual behavior, parents should not immediately conclude that this means that the child is already homosexual. Sexual behavior during adolescence does not necessarily predict future sexual orientation. It is estimated that 6% of females and 17% of males have had at least one homosexual experience during adolescence. Children sexually explore in the same way that they explore other parts of their environment. The first task of the physician after discovering that a child has engaged in homosexual activity is to help the younger child feel safe and less guilty. Parents should avoid suspicious, scolding, threatening, shaming, or guilt-inducing attitudes or behaviors toward the child. The physician can serve as a model for the parent through his or her own calm, sensitive, careful exploration of feelings and behavior with the child. The physician should expect denials on the part of the child and avoidance of and embarrassment with the subject, but discussion helps the child understand that sexual behavior is comprehensible and that sexual feelings and curiosity are normal. It is important to know whether the child's information and understanding of sexual matters are appropriate for his or her age.

If the same-sex behavior involves another child in the family, he or she should be treated in the same manner. If an older child is the initiator or seducer, he or she should be told clearly and firmly that such behavior will not be tolerated and that he or she will be expected to act with responsibility and control. The older child should talk with a physician or mental health professional; if concerns about emotional and social adjustment become evident, referral for a psychiatric evaluation is indicated. Physicians must not let their own negative feelings aggravate the negative feelings that parents might have for an older child seen as a perpetrator, especially if the older child is not a member of the younger child's family. The physician may need to help the parents of exploited children refrain from ill-considered acts of revenge against the offenders. On the other hand, if there has been physical violence or psychologic coercion, both psychiatric and legal interventions are indicated.

In taking a history of sexual behavior, the pediatrician should not presume exclusively heterosexual behavior. Confidentiality must be maintained, except in sexual abuse cases. Depending on the patient's prior experience, the physical examination should include an assessment of possible sexually transmitted diseases (STDs). All sexually active males should have appropriate laboratory testing for STDs. Immunization for hepatitis B is recommended and should be provided for all

males who anticipate having sex with another male. Human immunodeficiency virus (HIV) testing with the necessary consent is appropriate in these situations. Counseling before and after HIV testing is also necessary. Homosexual activity between adolescent girls is associated with a far lower risk of STDs. However, both HIV infection and other STDs can be transmitted during lesbian sexual activity, especially if one of the partners has also had sex with a man.

When the social opprobrium is considered, it is not surprising that homosexual feelings and wishes create psychologic conflicts in adolescents. Studies suggest that 3–30% of adolescent suicides are attributed to conflicts regarding sexual orientation. In a Minnesota study, 28.1% of gay/bisexual males (grades 7–12) had attempted suicide at least once, compared with 4.2% of heterosexual males of the same age. Although a greater percentage of lesbian adolescents attempted suicide than heterosexual females (20.5% compared with 14.5%), the difference was not statistically significant (see Chapter 24). Troiden's model of homosexual identity development helps elucidate the stages associated with sexual orientation acceptance. These include sensitization, i.e., the awareness of being different because of same-gender attraction; sexual identity confusion, i.e., turmoil often related to trying to reconcile one's feelings with negative societal stigmatization; sexual identity assumption, i.e., acknowledgment of one's own gay identity; and integration and commitment, i.e., incorporation of sexual identity into a positive self-acceptance.

Treatment.

In spite of some anecdotal reports to the contrary, very little can be done to change one's sexual orientation. Even in cases in which individuals have expressed the desire to change, significantly less than half of those who have tried have been able to change sexual orientation with various behavioral and dynamic therapies. Often, attempts to change sexual orientation lead only to additional guilt and further stigmatization. Psychotherapy is more appropriately used for concurrent disorders (separation anxiety disorder, conduct disorder, dysthymic disorder, depression) and to help with the conflict that often ensues as one moves toward sexual orientation acceptance. Families usually need assistance in coping with this knowledge and their attendant anger and disappointment. Children need help in understanding how to cope with the reactions of others.

Chapter 27 - Pervasive Developmental Disorders and Childhood Psychosis

Richard Dalton
Marc A. Forman
Neil W. Boris

Pervasive developmental disorders include autistic disorder, Asperger disorder, childhood disintegrative disorder, and Rett disorder.

27.1 Autistic Disorder

Autism develops before 36 mo of age and is typically diagnosable at 18 mo of age. It is characterized by a qualitative impairment in verbal and nonverbal communication, in imaginative activity, and in reciprocal social interactions.

Epidemiology.

Recent studies show prevalence rates ranging from 10 to 20 per 10,000 children. There is controversy regarding whether the incidence of autism is increasing. The disorder is much more common in males than females (3–4:1). Autism can be associated with other neurologic disorders, particularly seizure disorders, and to a lesser extent, tuberous sclerosis and fragile X syndrome.

Etiology.

The cause of autism is multifactorial. Genetic factors play a significant role. There is a 60–90% concordance rate for monozygotic twins and less than 5% concordance rate for dizygotic twins. What is actually inherited is not entirely clear; language and cognitive abnormalities are more common in relatives of autistic children than in the general population. In various case reports on autistic children, anomalies have been reported in all but three chromosomes, but most promising may be the findings of deletions and duplications in chromosome 15.

Theories of causation have also centered on a variety of other possibilities, especially pre- or perinatal brain injury. Deficits in the reticular activating system, structural cerebellar changes, forebrain hippocampal lesions, and neuroradiologic abnormalities in the prefrontal and temporal lobe areas have been documented. Autistic children have also been reported to have an increase in brain volume in several regions, and idiopathic infantile macrocephaly has been associated with autism. Studies also demonstrate anatomic changes in the anterior cingulate gyrus, an area of the brain associated with decision-making and the ascription of feelings and thoughts. Abnormal neurochemical findings have also been associated with autism, with dopamine, catecholamine, and serotonin levels or pathways implicated. However, the literature on brain structure and function in autistic children is conflicting and there is no diagnostic imaging or other test for autism.

Contrary to notions in vogue in the past, autism is not induced by parents. A number of excellent epidemiologic studies have established that there is no association between the use of measles-mumps-rubella vaccine and autism.

Clinical Manifestations.

Early measurable diagnostic symptoms and signs of autism include poor eye contact, little symbolic play, limited joint attention or orienting to one's name, and reliance on nonverbal communication with delay in use of words. Stereotypical body movements, a marked need for sameness, and a very narrow range of interests, are also common. The autistic child is often withdrawn and spends hours in solitary play. Ritualistic behavior prevails, reflecting the child's need to maintain a consistent, predictable environment. Tantrum-like rages may accompany disruptions of routine. Eye contact is typically minimal or absent. Visual scanning of hand and finger movements, mouthing of objects, and rubbing of surfaces may indicate a heightened awareness and sensitivity to some stimuli, whereas diminished responses to pain and lack of startle responses to sudden loud noises reflect lowered sensitivity to other stimuli. If speech is present, echolalia, pronoun reversal, nonsense rhyming, and other idiosyncratic language forms may predominate. Early diagnosis of children at risk for autism can be facilitated by the use of the Checklist for Autism in Toddlers (CHAT), a screening instrument. Research using home movies of 1-yr birthday parties has shown that children at risk for autistic disorder can be reliably identified at this age. These children do not share affect with caregivers by pointing, communicating interest, or sharing in joint attention.

Intelligence by conventional psychologic testing usually falls in the functionally retarded range; however, the deficits in language and socialization make it difficult to obtain an accurate estimate of the autistic child's intellectual potential. Some autistic children perform adequately in nonverbal tests, and those with developed speech may demonstrate adequate intellectual capacity. Occasionally, an autistic child may have an isolated, remarkable talent, analogous to that of the adult savant.

Although first described as a social illness, subsequent studies have focused on the communicative and cognitive deficits of autism and, particularly, on the types of cognitive processing deficits most apparent in emotional situations. Autistic children also show deficits in their understanding of what the other person might be feeling or thinking, a so-called lack of a “theory of mind.” On some psychologic tests, children with autism pay more attention to specific details while overlooking the entire gestalt

of the object, demonstrating a “lack of central coherence.”

Treatment.

Considerable advances have been made in the treatment of autism, especially within the educational, psychosocial, and biologic areas. There is compelling evidence that intensive behavioral therapy, beginning before 3 yr of age and targeted toward speech and language development, is successful both in improving language capacity and later social functioning. Treatment is most successful when geared toward the individual's particular behavior patterns and language function. Parent education, training, and support is always indicated, and pharmacotherapy for certain target symptoms may be helpful.

Working with families of autistic children is vital to the child's overall care. Children with autism require alternate educational approaches even when language capacity is near normal. Such services in general have not yet been sufficiently developed to provide adequate support and continuity of care. One successful educational model is the program for the Treatment and Education of Autistic and Related Communication Handicapped Children (TEACCH). The following treatment principles are emphasized: use of objective measures such as the Childhood Autism Rating Scale (CARS) to measure behavior and behavioral change; enhancement of skills and acceptance by the environment of autism-related deficits; use of interventions based on cognitive and behavioral theories; use of visual structures for optimal education; and multidisciplinary training for all professionals working with autistic children. Educational programming should begin as early as possible, preferably by age 2–4.

Older children and adolescents with relatively higher intelligence but with poor social skills and psychiatric symptoms (e.g., depression, anxiety, obsessive-compulsive symptoms) may require psychotherapy, behavioral or cognitive therapy, and pharmacotherapy. Typically, behavior modification is a major part of the overall treatment for older children with autism. These procedures include enhancement (i.e., rewards emphasizing appropriate choice) and reduction (extinction, time-out, punishment). Ethical concerns about vigorous aversive therapy approaches have led to specific guidelines. Social skills training

is also currently used as a treatment modality and appears effective, especially in a group format.

Unfortunately, there are unfounded claims of beneficial results from many unproven therapies for autism, almost all of which have not been subjected to scientific study. Those studies that have been done have discredited the technique of facilitated communication and have shown that auditory integration therapy has no positive effect. Claims of beneficial results from the use of secretin, a peptide hormone that stimulates pancreatic secretion, have not been substantiated by scientific study. Similarly, the dietary supplement N, N-dimethylglycine has no benefit.

Because a subgroup of autistic children present with psychiatric symptoms, pharmacotherapy is sometimes used to ameliorate target behaviors. The behaviors include hyperactivity, tantrums, physical aggression, self-injurious behavior, stereotypes, and anxiety symptoms—especially obsessive-compulsive behaviors. The older neuroleptics were limited in their usefulness because of their tendency to produce extrapyramidal symptoms and tardive dyskinesia. Open label trials of the newer atypical neuroleptics (e.g., risperidone, olanzapine) have shown effectiveness in treating the above behaviors, and in some instances, have also improved social relatedness (see Chapter 28.2).

Naltrexone, an opiate antagonist, was also originally touted as useful, especially for self-injurious behavior, but its utility has not yet been proven. Clomipramine, a tricyclic antidepressant with serotonin reuptake inhibition action, has demonstrated usefulness in reducing compulsions and stereotypes in autistic children. However, it does lower the seizure threshold, can cause agranulocytosis, and has cardiotoxic and behavior toxicity effects. Other medicines used to treat psychiatric symptoms in autistic children include the stimulants, the serotonin reuptake inhibitors (SSRIs), and clonidine. The SSRIs, in particular, appear to be somewhat effective in diminishing hyperactive, agitated, and obsessive-compulsive behaviors, although there have not yet been sufficient, controlled studies regarding their utility (Chapter 28.2).

Prognosis.

Some children, especially those with speech, may grow up to live self-sufficient, employed, albeit isolated, lives in the community. Many others remain dependent on family for their everyday lives or require placement in facilities outside the home. Because early, intensive therapy may improve language and social function, delayed diagnosis may lead to worse outcome. There is no increased risk for the development of schizophrenia in adulthood but the cost of delayed diagnosis across the life span is high. A better prognosis is associated with higher intelligence, functional speech, and less bizarre symptoms and behavior. The symptom profile for some children may change as they grow older and seizures or self-injurious behavior becomes more common.

27.2 Asperger Disorder

Children with this disorder have a qualitative impairment in the development of reciprocal social interaction, often demonstrating repetitive behaviors and restricted, obsessional, idiosyncratic interests. They do not, however, have the severe language impairments that characterize autism. Though somewhat socially aware, these children appear to others to be peculiar or eccentric. Prevalence is estimated to be approximately 3/1,000 children. This disorder may represent a higher-functioning form of autism, although this distinction remains controversial. Group social skills training is the hallmark of intervention, although children with Asperger disorder appear to be at high risk for other psychiatric disorders, particularly oppositional-defiant disorder and mood disorders.

27.3 Childhood Disintegrative Disorder

This disorder, also known as Heller dementia, is a rare condition of unknown cause, characterized by normal development up to 2–4 yr followed by severe deterioration of mental and social functioning, with regression to a very impaired “autistic” state. Language, social skills, and imagination are profoundly affected; bowel and bladder control may be lost; and motor stereotypes and seizures are often present. Although this condition may be the result of an underlying neurologic illness, none has been identified. The prognosis is always poor.

27.4 Rett Disorder

This is an X-linked dominant disorder affecting girls almost exclusively; boys affected with the disorder die at birth. It has a prevalence of 1/10,000. Development proceeds normally until approximately 1–2 yr of age, at which time language and motor development regress and acquired microcephaly becomes apparent. These girls present with midline, stereotypic hand-wringing, ataxia, breathing dysfunction, bruxism, scoliosis, and profound intellectual handicap. Autistic behaviors are typical, but over time, social relatedness may improve. Lower limb involvement may progress, leading to wheelchair dependency later in life. Postmortem examinations have revealed greatly reduced brain size and weight as well as number of synapses. A gene that causes Rett syndrome has been identified; it encodes the methyl CpG-binding protein 2 (MeCP2).

27.5 Childhood Schizophrenia

Psychotic reactions in older children tend more closely to resemble the psychoses of adulthood, and the same diagnostic criteria apply. Psychosis associated with a mood disorder, such as bipolar illness, is discussed in Chapter 23 .

Clinical Manifestations.

In *childhood schizophrenia,* prominent symptoms include thought disorder, disorganized speech, delusions, and hallucinations. The latter two symptoms, in addition to later onset, higher intelligence scores, and fewer perinatal complications, differentiate schizophrenia from autism. As the symptoms imply, schizophrenic children are typically severely impaired. They may have paranoid delusions, aggressive behavior, hebephrenic silliness, social withdrawal, and alternating moods not apparently related to environmental stimuli.

The prevalence of adult schizophrenia is 1%. The typical age of onset is late adolescence to early adulthood. Early-onset schizophrenia (e.g., prepubertal or early adolescence) is very rare. As infants, half of schizophrenic children are said to have had abnormally delayed development, and unusual sensory sensitivities. Schizophrenic children show significant premorbid maladjustments, including social withdrawal, disruptive behaviors, developmental delays, and speech and language problems. The onset of the disorder is usually insidious. Auditory hallucinations are seen in 80% of schizophrenic children. Delusions and formal thought disorders usually do not present until mid-adolescence. Children with early-onset schizophrenia show preliminary evidence of progressive ventricular enlargement, decrease in total cerebral volume, and decline in intellectual functioning. The prognosis is poor. The symptoms in childhood that most predict psychotic adult psychopathology are affective blunting and disturbed interpersonal relationships, as opposed to delusions and hallucinations.

Individuals with various psychotic processes are often misdiagnosed as schizophrenic. In a recent National Institute of Mental Health childhood-onset schizophrenia (COS) study, over 1,300 children were referred with a putative diagnosis of COS. After various screening and evaluation procedures, about 5% were actually labeled with COS and accepted into the research program. The majority of misdiagnosed patients were later noted to suffer with bipolar disorder, major depressive disorder with psychosis, and psychosis, not otherwise specified.

Treatment.

A multimodal therapeutic approach is necessary to manage this illness. Parent training is necessary to teach effective techniques to modify the schizophrenic child's behavior to improve social functioning. Individual therapy designed to build a positive alliance is also very important. School and community liaison work can establish and maintain a day-to-day schedule for the patient. Neuroleptic therapy is often effective in managing hallucinations and psychotic delusions. The use of haloperidol has largely been replaced by newer atypical antipsychotics such as risperidone and olanzapine. These medications appear to have lower risks for extrapyramidal symptoms and tardive dyskinesia. However, weight gain is common with atypical neuroleptics. Clozapine appears to be the most effective antipsychotic medication for refractory cases, but the risk of agranulocytosis and seizures limits its use (see Chapter 28.2).

Chapter 28 - Psychologic Treatment of Children and Adolescents

Richard Dalton

28.1 Illness and Death

All clinical phenomena relate to various organizational levels: molecular, anatomic, physiologic, intrapsychic, interpersonal, familial, and social. Accordingly, physicians should focus on patients' discomfort rather than on a categorization of clinical manifestations as either organically or psychologically determined. The psychologic aspects of illness should be evaluated from the outset, and physicians should act as a model for parents and children by showing interest in a child's feelings and demonstrating that it is possible and appropriate to communicate discomfort in verbal, symbolic language.

For *hospitalized children,* potential challenges include coping with separation (Chapter 33); adapting to a new environment; adjusting to multiple caregivers; often associating with very sick children; and sometimes experiencing the disorientation of intensive care, anesthesia, and surgery. To help mitigate potential problems, a preadmission visit to the hospital is often important to meet the people who will be offering care and to ask questions about what will happen. For children younger than age 5–6 yr, parents should room with the child if feasible. Creative and active recreational or socialization programs, with liberal visiting hours (including visits from siblings), and chances to act out feared procedures in play with dolls or mannequins all are helpful. Sensitive, sympathetic, and accepting attitudes toward children and parents by the hospital staff are very important. There is often an underlying tension between the hospital caregivers and the parents. Hospital routines and schedules often serve to complicate the relationship between parents and hospital workers. Guilt and anger can result, unnecessarily complicating an already difficult situation (Chapter 54).

Ambulatory care in clinics or offices where patients receive discontinuous care from a series of physicians whose intercommunication is often limited may create a problem. Parents often become confused and unable to verbalize major concerns about their children. Recommendations for care may become inappropriate or irrelevant, and compliance with advice or directions becomes poor. At the end of any initial diagnostic or management activity, physicians should habitually inquire whether there are other things parents or children may wish to talk about during this

visit. In busy emergency rooms, conflicting expectations between how the professional staff expects the emergency room to be used and what patients actually need can lead to confusion. When these different expectations are critically examined, ways may be found to deal more effectively with the patterns of use of emergency services.

With *chronically or fatally ill children,* patients and parents experience each symptom as a threat to physical integrity and life. The more serious the clinical state, the greater the intensity of the emotions aroused (see Chapters 33 , 37 , and 38). In dealing with chronic illness that shortens life, parents need physicians' early support in developing a relatively guilt-free understanding of the disease and how to manage it. They need guidance to help them comfortably answer their child's questions about the disease. Parents of critically or fatally ill children may creatively support each other in group meetings under the professional guidance of physicians, psychologists, or social workers. Young children take most cues from their parents. With older children, especially adolescents, parents must be prepared to deal with the anger of their children because of their fate. Children need both the parents' psychologic strengths and resources and the physician's availability and objectivity. The siblings of an ill child require information about the disease and the support and attention of the parents for their own needs.

Physicians must stand for hope and for relief of discomfort, ready to help parents and children avoid emotionally crippling psychologic handicaps. In potentially *fulminant lethal processes,* the intensity of parental anxiety, guilt, and despair may be greater than it is with more chronic illnesses (Chapters 33 , 38 , and 54 ; also see Chapter 60 for discussion of transplant issues). A hospital team approach representing medical, nursing, psychologic, and social work disciplines, among others, should provide support. The primary physician needs to stay involved and close to the child and to the clinical situation.

After *the death of a child,* the parents need opportunities to talk out their feelings with the physician, one of whose goals should be to help them avoid psychologically encapsulating the lost child in an unmourned state (see Chapter 33). Physicians need the patience to listen (both to the stated and to the implied questions and misconceptions), to answer questions, and to help families with funeral arrangements (see Chapters 33 , 38 , and 64).

28.2 Psychopharmacology

Using drugs to modify children's behavior is controversial. Their effects on behavior are influenced by the maturity of the central nervous system, by intrapsychic and psychosocial factors, by the personality or charisma of the physician prescribing them, by the problem itself, and by the milieu (e.g., patient, parents, time of day given). Although potentially helpful, psychiatric medications can cause very serious side effects. Even though some guidelines for their use are offered in Table 28–1 , only clinicians with appropriate training and experience should prescribe the antipsychotics, mood stabilizers, and tricyclic antidepressants.

Neuroleptics are appropriately used for hallucinations, delusions, thought disorders, and severe agitation. They are primarily indicated for children and adolescents suffering with schizophrenic disorders, mood-congruent and mood-incongruent psychotic reactions secondary to major affective disorders, autism presenting with stereotypic and withdrawal symptoms and self-abuse, and Gilles de la Tourette syndrome. This class of medicine is inappropriately used for anxiety, conduct disorder without extreme aggression, and attention deficit disorder.

Neuroleptics can be subdivided into typical (low-potency, mid-potency, and high-potency subtypes) and novel, atypical types (clozapine, risperidone, olanzapine, quetiapine, and ziprasidone). Thioridazine (Mellaril), a low-potency, high-dosage typical antipsychotic is no longer recommended for usage because of potential hepatotoxicity. Low-potency typical antipsychotics usually require a higher dose than the other neuroleptics for symptom remission. They tend to cause sedation, producing numerous anticholinergic side effects but comparatively fewer extrapyramidal symptoms. Mesoridazine is an example of a mid-potency medicine. It produces more extrapyramidal symptoms than the low-potency drugs. Thiothixene and haloperidol are high-potency medicines that produce, comparatively, the greatest number of extrapyramidal symptoms. Clozapine, an atypical neuroleptic, has efficacy in the treatment of negative schizophrenic symptoms. However, threatening side effects include agranulocytosis and seizure development. Although it is often effective when other agents are not, its use is often limited to refractory cases because of its toxicity. The other atypicals are a substantial improvement over the typical antipsychotic medications, not only because they appear to be more effective, but also because they are less likely to cause tardive dyskinesia and extrapyramidal symptoms. However, QTc prolongation on electroencephalographic studies and weight gain can be problematic.

The most worrisome side effect of the typical neuroleptics is the development of

tardive dyskinesia. This is characterized by choreoathetoid movements of the trunk, limbs, and facial musculature; these movements develop in approximately 20–30% of children treated long term with neuroleptics. Dyskinesia can occur during the treatment with the drug or after it has been discontinued, in which case it is referred to as *withdrawal dyskinesia.* This latter type of dyskinesia, the symptoms of which can include nausea, vomiting, diaphoresis, ataxia, oral dyskinesia, and various dystonic movements, is reversible in most cases, whereas the dyskinesia developing during drug use may not be reversible. The best instrument for the assessment of abnormal movements of children and adolescents is the Abnormal Involuntary Movement Scale (AIMS). Treatment of tardive dyskinesia involves decreasing or discontinuing the medication if possible, despite the fact that it has been noted that increasing the neuroleptic causes a temporary diminution of dyskinetic symptoms. Prophylactic measures involving drug-free holidays and periodic discontinuation of neuroleptics are also advisable to help mitigate the development of tardive dyskinesia.

Extrapyramidal symptoms, a Parkinson-like syndrome (akathisia, bradykinesia, torticollis, drooling, and involuntary hand movements, among others), develop in at least one fourth of children treated with neuroleptics. The imbalance created by the dopaminergic blocking action of the antipsychotic medication disrupts a needed balance between the dopaminergic system and the cholinergic system within the basal ganglia. The high-potency neuroleptics, which contain few anticholinergic properties, are the most likely to produce extrapyramidal symptoms. This syndrome can be treated by decreasing the neuroleptic or adding an anticholinergic agent (trihexyphenidyl HCl [Artane], benztropine mesylate [Cogentin]).

Neuroleptic malignant syndrome, a rare side effect of neuroleptic use, can be fatal. Its development is heralded by a high fever and a “lead pipe” stiffness of the extremities. Patients' creatinine phosphokinase level is also markedly elevated. Immediate discontinuation of the medicine and supportive care are necessary during the early part of the syndrome.

Stimulant medications are used to treat the signs and symptoms of attention-deficit/hyperactivity disorder (see Chapter 29.2). Although the mechanism of action is not entirely clear, these medications increase children's ability to attend, improve classroom behavior, and increase social acceptance of affected children in various situations. These stimulants should be used concurrently with individual, family, and community therapy.

Antidepressants and *mood stabilizers* are useful in the treatment of affective disorders. Antidepressants generally are effective for depression, whereas lithium, carbamazepine, valproate, and lamotrigine have shown efficacy in the treatment of mania. Adult patients with bipolar and unipolar disorders are often treated with long-term pharmacotherapy, and this is becoming more common in childhood and adolescence. Because of the propensity of tricyclic antidepressants to cause heart block, a pretreatment electrocardiogram (ECG) and follow-up ECGs are necessary. Heart block usually takes at least a few weeks to develop. Although deaths in school-aged children taking desipramine have been reported, sudden deaths have not been reported in conjunction with the use of other tricyclics or with other nontricyclic antidepressants. Before prescribing tricyclics in general and desipramine in particular, clinicians must procure a detailed medical history, including examination of a patient's cardiovascular system and ascertainment of any family history of cardiac disease (including unexplained syncope and sudden death). A child with a suspicious history or with abnormal ECG findings should have a pediatric or cardiologic assessment before these medicines are used. The desipramine dose should not exceed 3.5–5.0?mg/kg. A pretreatment lithium evaluation includes thyroid studies, renal function tests, and electrolyte determinations. Lithium blood levels should also be determined while patients are taking the medication. Prolonged use of lithium may cause hypothyroidism.

Serotonin reuptake blockers, especially fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil), are effective in patients with mild depressive symptoms, anxiety, and compulsions. Paroxetine is especially useful because of its relatively short half-life and lack of side effects. Clonidine has been partially successful in treating children with attention-deficit/hyperactivity disorder and in those who have a personal history of tics (including Gilles de la Tourette syndrome).

Carbamazepine, an *antiepileptic* medicine, is effective in the treatment of mania and episodic dyscontrol syndrome. *ß-Blocking agents* (nadolol [Corgard]) appear to decrease aggressiveness in mentally retarded patients. *Opiate antagonists* significantly change some behaviors in autistic children and have promise in the treatment of self-injurious behavior in severely and profoundly mentally retarded individuals. Clomipramine (Anafranil) is efficacious in the treatment of obsessive-compulsive disorder. Seizures have been reported secondary to its use, however.

Some parents are adamantly opposed to the use of psychotropic medications. If drugs are used, they should be used for as short a time as possible. As with any clinical disorder, physicians should

---

TABLE 28.2-1 -- **Psychopharmacology**

Medication Class	Use	Dosage	Side Effects/Toxicity/Ca

Antipsychotics—Traditional	**All:** severe agitation; psychosis; mania; stereotypic movements; self-abuse; extreme aggressiveness; Tourette		**All Classes:** Sedati weight gain, anticholinergic effec (dry mouth, blurred vision; constipation) hypersensitivity reac (hepatic, skin); blooc dyscrasias; parkinsc neuroleptic malignai syndrome; orthostat hypotension; agranulocytosis and seizures (especially clozapine) **N.B.:** Thioridazine (Mellaril) is no longe recommended beca of hepatotoxicity **N.B.:** Tardive dyskir is a potential side ef
Low-Potency/High-Dosage Chlorpromazine (Thorazine)		Initial: 10–30?mg/24?hr in single or divided doses. Maintenance: 100–900?mg/24?hr in divided doses	
Mid-Potency/Mid-Dosage Mesoridazine (Serentil)		10–75?mg/24?hr in divided doses	
High-Potency/Low-Dosage Haloperidol (Haldol)		Initial: 0.5–1?mg/24?hr in single or divided doses	
Trifluoperazine (Stelazine) Thiothixine (Navane)			
Antipsychotics—Novel (Atypical)			Same general side effects as Traditiona Antipsychotics
Clozapine (Clozaril)		Initial: 12.5–25?mg/24?hr; then increase by 25–50?mg/24?hr; maintenance dose: 250–500?mg/24?hr in divided doses	Seizures, agranulocytosis, we gain
Risperidone (Risperdal)		Initial: 0.5?mg bid; then increase by 0.5?mg each 3–4 days to 2–4?mg/24?hr	Weight gain, mild EI increase in Prolactin levels, prolongation QTc
Quetiapine (Seroquel)		Initial: 25?mg bid; then increase by 50–100?mg every 2–3 days to 50–500?mg/24?hr	Sedation, weight gai
Olanzapine (Zyprexa)		Initial: 2.5–5?mg hs; if necessary, increase by 2.5?mg every 3–4 days to 5–15?mg/24?hr	Sedation, weight gai prolongation of QTc
Ziprasidone (Geodon)		40–80?mg/24?hr in divided doses	Prolongation of QTc
Stimulants	**All Drugs:** ADHD (with and without behavioral acting out): Narcolepsy (methylphenidate, dextroamphetamine)		Lower seizure thresl insomnia, decreasec appetite, possible w loss; irritability and tearfulness; abdomi pain, headache; ele systolic blood press development and worsening of tics; possible subnormal height and weight gı Possible precipitatio hypomania in bipola patients; pemoline (Cylert) is no longer recommended beca of hepatotoxicity
Methylphenidate (Ritalin, Concerta, Metadate ER)		Ritalin: 0.3–1.0?mg/kg/24?hr in divided doses; Concerta: 18?mg in single dose, increase to 36?mg if necessary; Metadate ER: 10?mg increased to 60?mg/24?hr if necessary	

Dextroamphetamine (Dexedrine, Adderall)		Dexedrine: 0.2–0.6?mg/kg/24?hr in divided doses; Adderall: Initial: 2.5–5?mg; increase by 2.5–5?mg/24?hr to 60?mg/24?hr (Narcolepsy)	
Antidepressants			
Tricyclics			
Desipramine (Norpramin)	Major depressive disorder in mid to late adolescence; ADHD (12 yr and older); separation anxiety disorder	For major depression disorder and separation anxiety disorder, 2–3?mg/kg/24?hr in divided doses. (Therapeutic blood level, 100–250?mg/mL)	Possible sudden de doses >3.5–5?mg/k hypertension, orthos hypotension, cardia arrhythmia, lengthe of PR or QRS interv ECG; overdose lea death
Imipramine (Tofranil)	As above; enuresis	As above. For enuresis usually 25–50?mg qhs (continued for at least 4–6 mo after remission of enuresis)	As above
Clomipramine (Anafranil)	Obsessive-compulsive disorder (OCD)	Starting dose of 25?mg, which is increased slowly (2–3 wk) to either 100?mg or 3?mg/kg (whichever is smaller) in divided doses. Thereafter, increase to a maximum of 250–300?mg	Seizures; overdose leading to death; ST wave changes on E conduction abnorma psychiatric changes including mania and confusion; weight ga hyperthermia; verti constipation
Selective Serotonin			
Reuptake Inhibitors			

Fluoxetine (Prozac)	Mild-moderate depression, anxiety, OCD	10–20?mg/24?hr (possibly higher for OCD)	Fluoxetine and its principal metabolite a long half-life (1–4 days). Can inhibit its metabolism; thus, a increase in dose ma result in a disproportionate inc in side effects. Drug interactions with compounds metabo by several isoenzym the cytochrome P 4 system (especially terfenadine, astemiz cisapride); gastrointestinal diffi (nausea, diarrhea, vomiting); CNS effe (agitation, disinhibiti jitteriness, headach insomnia); tremor; serotonin syndrome (fever, myoclonus, confusion, tachycar rigidity…) when take with MAO inhibitors L-tryptophan; mania self-injurious behavi and behavioral activ and dyscontrol
Paroxetine (Paxil)	As above	10–30?mg/24?hr	As above except sh half-life (24?hr); withdrawal sympto stopped abruptly
Sertraline (Zoloft)	As above	25–50?mg/24?hr with meals	Similar to paroxetin fairly inactive metab has longer half-life; exhibits linear relationship betwee dose and side effec
Fluvoxamine (Luvox)	OCD	Initial: 50?mg each night. Increase slowly to no more than 300?mg/24?hr in divided doses.	Similar to sertraline; interference with cytochrome P450 sy

Venlafaxine (Effexor)	Depression	37.5?mg/24?hr increased by no more than 37.5–75?mg/24?hr to a maximum 225?mg/24?hr in divided doses, with meals	As above, except fo interference with cytochrome P450 sy
Aminoketone			
Bupropion (Wellbutrin)	Depression, ADHD	Initial: 75–100?mg/24?hr increased slowly to 200–300?mg/24?hr (bid dosing); total daily dose should not exceed 450?mg	Seizures, restlessne agitation, weight los rashes, nocturia, ma flulike symptoms
Mood Stabilizers			
Lithium carbonate	Bipolar cycling typical of older adolescents and adults, some cases of unipolar illness, affective type of aggression	600–1,200?mg/24?hr (therapeutic blood level: 0.6–1.2?mEq/L)	Gastrointestinal disturbance, tremor, ataxia, confusion, cc death; hypothyroidis Once discontinued, lithium is often not a effective when resta Overdose leading to death
Carbamazepine (Tegretol)	Bipolar cycling including rapid cycling; aggressive behavior in organically impaired patients	Initial: 100–200?mg/24?hr increased to 400–1,000?mg/24?hr (therapeutic blood level: 8–12?µg/mL)	Fever, sore throat, hematologic problen (white cell decrease dizziness, drowsines neuromuscular disturbance, blurred vision; overdose lea to death
Valproic acid (Depakene)	Rapid cycling bipolar disorder, aggression	Initial: 125–250?mg/24?hr or 10–15?mg/kg; increase by 5–10?mg/kg/24?hr up to 60?mg/kg/24?hr in divided doses (therapeutic blood level: 50–120?µg/mL)	Hepatic failure (usua the first few months treatment); younger children (under 10 y especially under 2 y patients with prior he disease history, thos multiple anticonvulsa those with severe se history plus mental retardation, and thos with congenital meta disorders are especi vulnerable. Obesity, defects in pregnancy possible clotting problems; depressio nausea, vomiting, indigestion (at initiat therapy), rashes; overdose leading to and possibly death; pancreatitis; polycys ovary syndrome
Lamotrigine (Lamictil)	Bipolar depression, especially Bipolar II depression; dysphoric mania, rapid cycling Bipolar II	Initial: 25?mg/24?hr during first 2 weeks; if necessary, increase by 50?mg/24?hr each week to a maximum of 300–400?mg/24?hr **N.B.:** NOT yet recommended for patients under 18 yr	Sedation, nausea, headache; Rash in 1 of patients (Risk of Stevens-Johnson reaction); Concurrer with valproic acid do the lamotrigine bloo level
Antihypertensives			
Clonidine (Catapres)	Hyperactivity; aggression associated with ADHD; secondary use in tic disorder	0.1–0.25?mg/24?hr	Sedating bradycardi hypotension; withdra symptoms; sudden deaths reported whe used with stimulants
Guanfacine (Tenex)	Aggression associated with ADHD; tic disorder	0.5–1?mg qhs	Sedation, headache (less hypotension th clonidine)

ADHD, attention-deficit/hyperactivity disorder; BUN, blood urea nitrogen; CBC, complete blood cou nervous system; ECG, electrocardiogram; EPS, extrapyramidal symptoms; MAO, monoamine oxid obsessive-compulsive disorder.

initially avoid using several medications at the same time and should not shift back and forth from one medication to another when no immediate response occurs. Because psychotropic medications have significant biochemical effects on developing children, it is important to give an appropriate explanation to parents and children about the rationale for medication. Parents and children must have an opportunity to discuss their feelings and thoughts about psychotropic medication use in general and the specific drug that is ordered. Even with thought disorders, in which pharmacotherapy has a firmly established place, medication is rarely if ever the sole treatment indicated. The complexity of emotional conditions demands an integrated approach involving various therapies: psychodynamic (individual, family, or group), behavioral, milieu, medication, and the use of resources in the family, school, and community. These factors must be knowledgeably selected, judiciously coordinated, and skillfully applied to ensure maximal benefit for a child.

28.3 Psychotherapy

When it has been determined that psychopathology exists in a child or within a family and that it requires intervention, a pediatrician may develop and implement the therapeutic plan or may refer to a mental health consultant. The choice of treatment should be left to the consultant, with the referring physician reassuring the family and patient that close communication with the consultant will be maintained. The primary physician should continue to evaluate the child's progress throughout the treatment process and to provide medical care for the patient.

There are many types of *individual psychotherapy*. Most involve the development of an alliance with patients that provides an opportunity to look at the problems precipitating therapy. Younger children often express their concerns and developmental issues in *play therapy,* a specific modality designed to foster symbolic and metaphoric individual expression. Older children and adolescents are more likely to participate in talking during therapy. *Dynamic therapy* is designed to understand the psychologic motivations for a child's problems and to develop a therapeutic process based on that understanding. *Behavior therapy* and *cognitive-behavior therapy* are especially useful in treating anxiety, depression, and some behavioral problems.

There are several types of *family therapy:* directive, structural, strategic, and object-relations. In each, the therapist works primarily with the family to impart understanding or to help organize change. A particular directive approach, *parent management training,* is very useful in treating behavioral problems. This approach involves training parents to respond in specific and consistent ways to a child's behavior.

Group therapy is especially useful for children suffering from poorly developed social skills. Group therapy for preadolescents tends to emphasize structured activities through which therapist and children alike can discover how they relate to each other and find ways to change. It is an especially profitable approach for treating the social problems of adolescents.

Barriers to involving the generalist or pediatrician in psychotherapeutic activities with children include a presumed lack of time and lack of adequate conceptual background. Although psychotherapy primarily emphasizes listening and interviewing, two skills important to all fields of medicine, experience is an important and necessary asset for psychotherapists.

28.4 Psychiatric Hospitalization

Psychiatric hospitalization of a disturbed or emotionally ill child in a general, pediatric, or psychiatric hospital is at times helpful or necessary, and it may serve a number of functions. In children with many psychosomatic disorders or in a suicidal or drugged adolescent, indications for hospitalization may be medical as well as psychiatric. If treatment of a child in a psychiatric hospital is thought necessary, consultation with a child psychiatrist is essential for decision-making and planning. The indications for admission include thought, behavior, and affect that are so irrational that they will not respond to less restrictive therapy; complex psychiatric problems that require skilled medical and nursing care; extremely disturbed family interactions that contribute to problematic behavior or interfere with needed care; and dangerous behavior that cannot otherwise be managed. Admission to residential treatment reflects the family's decompensation as often as the child's.

Chapter 29 - Neurodevelopmental Dysfunction in the School-Aged Child

29.1 Patterns of Development and Function*

Desmond P. Kelly

A neurodevelopmental function is a basic brain process that may be needed for learning and productivity. Neurodevelopmental variation refers to the differences in neurodevelopmental strengths and weaknesses that exist between individuals and that can change over time. Wide variations exist among individuals, and these differences need not represent pathology or abnormality. Neurodevelopmental dysfunctions reflect disruptions of neuroanatomic structure or psychophysiologic function and may be associated with academic underachievement, behavioral difficulties, and problems with social adjustment.

Etiology.

Multiple factors and diverse causes underlie neurodevelopmental dysfunctions. These include genetic, medical, environmental, and sociocultural influences. Molecular genetic studies have identified some of the genes that contribute to

* This chapter is a revision of the chapter in the 16th Edition authored by Melvin Levine, MD.

these dysfunctions. It is well established that reading disorders can be both familial and heritable, and investigations have linked some reading disabilities to a specific gene locus on the short arm of chromosome 6. Chromosomal abnormalities can lead to unique patterns of dysfunction such as visual-spatial difficulties in girls with Turner syndrome or language deficits in individuals with fragile X syndrome. Perinatal risk factors that have been associated with subsequent academic problems include very preterm birth, severe intrauterine growth retardation, and prenatal exposure to alcohol. Environmental toxins including lead, infections such as meningitis and AIDS, and brain injury from intraventricular hemorrhage or head trauma increase the risk for disorders of learning and attention. There have been conflicting reports regarding the contribution of persistent otitis media with effusion and conductive hearing loss to subsequent language problems. Environmental and sociocultural deprivation can also lead to, or at least potentiate, neurodevelopmental dysfunction. In individual cases, a definite cause usually cannot be ascertained.

Pathogenesis.

Advanced neuroimaging techniques are enabling confirmation of theories on the neurobiologic basis of learning problems. Functional magnetic resonance imaging has indicated decreased left temporoparietal cortical activity during a phonologic task of rhyming and decreased occipitoparietal extrastriate activity during an orthographic task of letter matching in children with reading disorder (dyslexia) compared to children with normal reading abilities. Studies of children with attention deficits have noted structural changes involving the frontal/striatal system and intra- and interhemispheric white matter projections. Quantitative electroencephalograms have been reported to be abnormal in 25–45% of children with learning disorders. However, the heterogeneity of study populations impedes generalization of these findings or clinical application for individual students.

Epidemiology.

It could be postulated that all individuals harbor some form of neurodevelopmental dysfunction. A high percentage of children encounter difficulty in a particular academic area during their school careers, although in most cases this is transient. The number of children whose neurodevelopmental dysfunction significantly impedes their academic success is lower. Estimates of the prevalence of learning disorders range from 3–10%, whereas attention deficits have been reported in 4–12% of school-aged children. These estimates are beset by differences in the definitions and criteria used for classification and diagnosis and depend on the method of assessment. Medical classification systems include the *Diagnostic and Statistical Manual of Mental Disorders* of the American Psychiatric Association (DSM) and the *International Classification of Diseases* (ICD) of the World Health Organization. The DSM differentiates *learning disorders* (reading disorder, mathematics disorder, and disorder of written expression) from *motor skills disorder* and *communication disorders.* Neurologists favor diagnostic terms such as dyslexia (reading disorder), dyscalculia (mathematics), or dysgraphia (writing). Within the educational system *specific learning disabilities* are defined by discrepancies between scores on tests of intelligence and tests of academic achievement that are used to determine eligibility for special education services.

Clinical Manifestations.

School-aged children with neurodevelopmental dysfunctions vary widely with regard to clinical symptoms. Their specific patterns of academic performance and behavior represent final common pathways, the convergence of many forces, including interacting cognitive strengths and deficits, environmental or cultural factors, temperament, educational experience, and intrinsic resiliency.

Eight areas of *neurodevelopmental function* (so-called neurodevelopmental constructs) are especially germane to understanding an academically delayed child.

ATTENTION.

Attention subsumes a series of control mechanisms through which the brain

regulates behavior and learning. Children with attentional dysfunction comprise a widely heterogeneous group who show various patterns of impairment of these controls (also see Chapter 29.2). The resulting symptoms may affect learning, behavior, or social interactions. Located in different parts of the brain, including the brain stem and frontal cortex, these controls are responsible for regulating the following:

1. *Mental energy* related to central nervous system (CNS) arousal, and the mobilization and distribution of mental effort: Children with diminished alertness and arousal are likely to exhibit signs of mental fatigue in a classroom. They often yawn, stretch, fidget, and daydream. They sometimes become overactive in an effort to attain a higher level of arousal. They may have difficulties falling asleep or awakening on time. They are apt to have difficulty allocating and sustaining their concentration, and their efforts at work may be erratic and unpredictable. Those affected by this form of weak control may manifest extreme *performance inconsistency.*
2. *Processing* and regulation of incoming stimuli: These children may have difficulty discriminating between important and unimportant information (also known as **selective attention**). Such weaknesses of saliency determination result in focusing on the wrong stimuli at home and in school. Weak saliency determination can make it difficult for a student to take notes, summarize information, or know what to study for a test. More overt forms of weak processing controls result in various types of distractibility, which may take the form of listening to extraneous noises instead of a teacher, staring out the window, or constantly thinking about the future. These children often show evidence of superficial concentration, not focusing with sufficient intensity to capture specific information. As a result, directions and explanations may have to be repeated or they may miss details such as changes in operational signs in mathematics. They may exhibit difficulties with cognitive activation, passively processing and not linking information with prior knowledge and experience, or over-relying on prior experience. Many of these children display insatiability and tend to be restless, to feel bored easily, and to require constant, high levels of stimulation or excitement.
3. *Production*, or the output of work, behavior, and social activity: Children with attention difficulties have a tendency to perform without previewing a likely outcome or thinking through what they are about to do. The consequent *impulsivity* can lead to careless mistakes in academic work and unintended misbehavior. They may show hyperactivity and have difficulty pacing, or doing tasks at the appropriate speed. Such children have difficulty with self-monitoring, not knowing how they are doing during and right after an academic endeavor or a behavior. As a result, they can get into trouble without realizing it. Finally, these children commonly are under-responsive to punishment and reward.

It is important to appreciate that most children with attentional dysfunction also harbor other forms of neurodevelopmental dysfunction. The latter can have a significant impact on the symptoms exhibited by a child. There is also considerable confusion and disagreement about the appropriate terminology to be applied to children with attentional difficulties. The *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, uses the term *Attention-Deficit/Hyperactivity Disorder* (ADHD) and makes a distinction between individuals who have trouble predominantly with inattention and those who exhibit substantial hyperactivity and impulsivity. It is likely that there are multiple subtypes of attention deficits.

MEMORY.

As children proceed through school, demand for the efficient use of memory progressively increases. Students are expected to be selective, systematic, and strategic in entering new procedures and factual data in memory. They must become

proficient in their use of both long- and short-term memory to file and retrieve rules, facts, concepts, and skills. By secondary school, rapid and precise recall is heavily emphasized. Not surprisingly, some students experience tremendous frustration when memory dysfunctions prevent them from satisfying academic demands.

Some children have difficulty with the initial registration of information in *short-term memory.* They have trouble quickly determining whether or not new information is relevant and transforming it to fit into short-term memory by condensing or shortening it. In some cases, children with attentional dysfunction have problems being selective and sufficiently alert to register salient information in memory. Others have difficulty registering newly introduced information at the level or depth needed to retain it. Registration weaknesses can be highly specific. Some students may have trouble with registering visual-spatial data in memory, whereas others may be deficient in the registration of language. Still others have a problem putting linear chunks or sequences of data in short-term memory.

Many children experience problems with *active working memory.* They are ineffective at temporarily suspending information in memory while they are working on it. Normally active working memory enables a student to keep in mind all of the different components of a task, such as a mathematics problem, while completing it. A student with an active working memory dysfunction, for example, might carry a number and then forget what it was that he or she intended to do after carrying that number. Active working memory during reading enables children to remember the beginning of a paragraph when they arrive at the end of it. It lets them remember what they intend to express in writing while they are attempting to remember where to place a comma or how to spell a particular word. It also enables the linkage between new incoming information that is held in short-term memory with prior knowledge or skills held in long-term memory.

Other youngsters experience frustration in their efforts at *consolidating* information in *long-term memory.* They are ineffective when filing data for later access. Ordinarily, consolidation in long-term memory is accomplished in one or more of four ways: (1) pairing two bits of information together (such as a group of letters and the English sound it represents), (2) storing procedures (consolidating new skills such as the steps in solving math problems), (3) classifying data in categories (e.g., filing all the insects together in memory), and (4) linking new information to established rules, patterns, or systems of organization (so-called rule-based learning).

Some children can register and consolidate facts and procedures in memory but seem to have inordinate difficulty *accessing or retrieving* these items when they need

them. They may have difficulty remembering one half of a paired association such as matching a name with a face or a historical event with a date. They are prone to encounter difficulty with *simultaneous recall,* the frequent need to retrieve several facts or procedures at once. Finally, some students exhibit *delayed automatization.* Not enough of what they have learned in the past is accessible to them instantaneously and with no expenditure of effort. Such skills as letter formation, the mastery of mathematic facts, and word decoding must ultimately become automatic if students are to make good academic progress.

LANGUAGE.

All of the basic academic skills are conveyed largely through language and it is not surprising that children with language dysfunctions usually have troubled educational careers.

Language disorder has many forms. Some children have particular problems with *phonology* (see Chapter 29.3). They experience unclear reception of English language sounds and are said to have difficulty with phonologic awareness. They may have trouble discriminating between and forming associations with the sounds of their native language. Language sounds are most often composed of more than one acoustic signal. For example, in English there are stop consonants, such as “puh” and “kuh.” For the brain to process these language sounds, it must accommodate the very rapid transition (about 30?msec in duration) from the sound “k” to the “uh” in “kuh.” In some cases, affected students may have trouble processing these acoustic signals within language sounds rapidly enough. Commonly, a weak phonologic sense has a negative effect on reading. A student with a poor appreciation of language sounds is likely to form unstable associative linkages between those sounds and visual symbols (i.e., letter combinations). It can be hard for them to conceptualize words as made up of language sound segments (phonemes); thus, their ability to break words down into their constituent sounds and then reblend them into pronounceable words is impeded. They may also have problems manipulating language sounds in their minds and blending them to form a word.

Semantic deficits are also common. Affected children have trouble learning the meaning of new words and using them appropriately. It is especially hard for them to develop a strong enough sense of how words relate to each other in their meanings. Other common language deficiencies include difficulty with *syntax* (word order), problems with *discourse* (paragraphs and passages), an underdeveloped sense of how language works (weak *metalinguistics*), and trouble with drawing appropriate inferences (i.e., supplying missing information) from language. Many adolescents fail to develop higher language functions. They have problems dealing with abstract and symbolic language, highly technical vocabulary, verbal concepts, densely packed verbal information in textbooks, foreign language learning, and figures of speech (including metaphors and similes).

It is common to distinguish between *receptive language dysfunctions* (those affecting understanding) and *expressive language dysfunctions* (those impeding production or communication). Children with primarily receptive language problems may have difficulty following instructions in the classroom, understanding verbal explanations, and interpreting what they have read. Expressive weaknesses include oromotor problems affecting articulation and verbal fluency. Some students experience difficulty with sound sequencing within words. Others find it hard to regulate the rhythm or prosody of their language. Their speech may be dysfluent, hesitant, and somehow inappropriate in its tone. Problems with *word retrieval* can also thwart expressive language fluency. Despite an adequate vocabulary, affected children have problems in finding exact words when they need them (as in a class discussion). They may reveal marked hesitation and keep substituting definitions for words (circumlocution). Still others with expressive impediments have trouble formulating sentences, using grammar acceptably, and organizing spoken (and possibly written) narrative. Some studies have linked expressive language dysfunction to delinquent behavior. This is especially true when an expressive language disorder occurs in a context of environmental deprivation or turmoil.

Students with strong language strengths may make use of their linguistic facility to overcome other learning problems. For example, it may be possible to verbalize one's way through a mathematics curriculum, thereby circumventing a tendency to be confused by predominantly nonverbal concepts (such as ratio, equation, and diameter).

SPATIAL ORDERING.

Visual processing abilities entail the appreciation of spatial attributes. Awareness of shape and position, and perception of relative size, foreground and background relationships, and form constancy are among the constituents of spatial ordering. Children with spatial ordering weaknesses may encounter some initial problems with letter and word recognition. Spelling may emerge as a weakness because these children commonly experience trouble recalling the precise visual configurations of words. In general, however, children who are confused about spatial attributes are unlikely to have

long-standing or serious academic problems unless their spatial weaknesses are complicated by additional academically relevant neurodevelopmental dysfunctions. At one time, it was thought that visual-spatial processing dysfunctions were a common cause of chronic reading disabilities; research, for the most part, has refuted this opinion.

Children with spatial ordering weaknesses may be late in discriminating between left and right. They may also show signs of gross motor clumsiness because they may be poor at making use of visual-spatial data to program motor responses, or they may have difficulty drawing and engaging in crafts activities.

TEMPORAL-SEQUENTIAL ORDERING.

Awareness of time and sequence is an important neurodevelopmental function. Students in school need to be able to manage time, to process and produce multistep explanations and procedures, and to develop memory capacity for extended sequences. The latter includes preservation of serial order in motor

procedures, in narrative, and in various mathematical algorithms.

Children who have difficulties with temporal-sequential ordering may be delayed in learning to tell time. They may have great difficulty in following multistep commands, performing acts that necessitate a sequence of steps in the proper order, mastering the months of the year, or organizing narrative. Affected children may also have trouble managing time. They may be frustrated in adhering to schedules, in learning the order of their classes in school, or in meeting deadlines.

NEUROMOTOR FUNCTION.

There are three distinct yet related forms of neuromotor ability relating to function in school: fine motor dexterity, graphomotor fluency, and gross motor coordination.

Problems with *fine motor function* can affect a child's ability to excel in artistic and crafts activities. They may also interfere with learning a musical instrument or mastering a computer keyboard. *Eye-hand incoordination* may be prominent because the child has trouble with the rapid and precise integration of visual inputs with specific motor plans for hand movements. Others may encounter difficulty remembering fine motor procedures such as tying shoelaces or playing a musical instrument. The term *dyspraxia* in general relates to difficulty in developing an ideomotor plan and activating coordinated motor actions to complete a task or solve a motor problem such as assembling a model.

Graphomotor function refers to the specific motor aspects of written output. Several subtypes of graphomotor dysfunction significantly impede writing. Some students harbor *weaknesses of visualization* during writing. They have trouble picturing the configurations of letters and words as they write. Their written output tends to be poorly legible with inconsistent spacing between words. Others have weaknesses in *graphomotor memory*, the ability to recall letter and number forms rapidly and accurately. They labor over individual letters and much prefer printing (manuscript) to cursive writing. Some of them exhibit signs of *finger agnosia* or difficulty with *graphomotor feedback;* they have trouble localizing their fingers while they write. As a result, they need to keep their eyes very close to the page and tend to apply excessive pressure to the pencil. Others struggle with *graphomotor production* deficits. Such students have trouble producing the highly coordinated motor sequences needed for writing. Although they may understand and be able to visualize what it is they need to write, they have difficulty assigning writing roles to specific muscle groups in their hands. This phenomenon has also been described as *dyspraxic dysgraphia*. It is important to emphasize that a child may show excellent fine motor dexterity (as revealed in mechanical or artistic domains) but very poor graphomotor fluency (with labored or poorly legible writing).

Some children exhibit *gross motor dysfunction.* They may have problems in processing "outer spatial" information to guide gross motor actions; affected children are inept at catching or throwing a ball because they cannot form accurate judgments about trajectories in space. Still others demonstrate diminished *body position sense.* They do not efficiently receive or interpret proprioceptive and kinesthetic feedback from peripheral joints and muscles. They are likely to be impaired when activities demand balance and the ongoing tracking of body movement. Others are unable to satisfy the motor praxis demands of certain gross motor activities. It is hard for them to recall or plan complex motor procedures (such as those needed for dancing, gymnastics, and swimming). Children with gross motor problems may incur considerable embarrassment in physical education classes. Gross motor weaknesses can lead to social rejection, withdrawal, and generalized feelings of inadequacy.

HIGHER-ORDER COGNITION.

This series of functions consists of various sophisticated thinking skills. Included are the formation of concepts, critical thinking, problem-solving skills, understanding and formulation of rules, brainstorming and creativity, and metacognition (i.e., the ability to think about thinking).

Children vary considerably in their capacities to understand the *conceptual bases of skills and content areas.* As students progress through their education, concepts become increasingly abstract and complex. New concepts are likely to contain previously encountered concepts. Some of these youngsters have a pervasive weak grasp of concepts, whereas others have difficulty only with concepts in highly specific domains (e.g., mathematics, social studies, or science). Some students prefer to conceptualize verbally, whereas others are more comfortable in forming concepts without the interposition of language (perhaps using visual imagery). Many of the best students try to solidify concepts both linguistically and nonverbally.

Problem-solving skills are an important part of mathematics and virtually every other subject in school. Children with good problem-solving skills are good strategists. They are excellent at previewing or estimating answers, coming up with several alternative techniques to meet challenges, selecting the best techniques, and monitoring what they are doing so that they can deploy alternative strategies as needed. Poor problem solvers, on the other hand, tend to be rigid or impulsive and fail to undertake challenges in a stepwise fashion. They may then encounter significant difficulties in course work that requires methodical strategy deployment and flexible problem solving.

Brainstorming skills are needed to develop a topic for a report, to think about the best way to undertake a project, and to deal with various other open-ended academic challenges. Some students cannot generate original ideas. They prefer to be told exactly what to do. They balk at having to devise a topic, deploy imagination, develop an argument, or think freely and independently.

Critical thinking skills represent another higher cognitive ability acquired during childhood. Successful students often display a keen ability to evaluate statements, products, and people using objective criteria. They are able to tease out their own personal biases and appreciate the viewpoints of others.

Metacognitive abilities are the capacity to think about thinking. Children with good metacognition are able to observe themselves thinking or studying. They can thereby develop an understanding of thought processes, enabling them to enhance their personal learning strategies and become more efficient and active learners. Those youngsters who lack metacognition tend to perform intellectual tasks the hard way. They are unlikely to appropriate effective techniques to study for a test, to write a report, or to meet other complex academic challenges.

SOCIAL COGNITION.

A student's social abilities are stringently tested throughout the school day and in the neighborhood after school. Increasing evidence shows that social cognition exists as a discrete area of neurodevelopmental function. There are multiple subskills within social cognition. These include the ability to enter smoothly into new relationships, the capacity to time and stage interactions effectively, the appropriate degree of sensitivity to social feedback cues, the knowledge

---

of how to resolve social conflict without aggression, the adaptive use of language in social contexts *(verbal pragmatics),* the ability to establish truly reciprocal (sharing) relationships with others (especially peers), and the inclination to overcome one's innate egocentricity to praise or nurture others. In addition to these skills, students need to be conscious of their own image development and to be adept at marketing themselves to peers and adults. Regrettably, some children have no idea of how adversely they are affecting others. Social skill deficits can exert an enduring negative effect on behavioral adjustment, mental health, and, ultimately, success in a career.

ACADEMIC EFFECTS.

Neurodevelopmental dysfunctions are likely to occur in varying clusters within individual children. Combinations of dysfunctions commonly result in academic delays, frequently affecting the acquisition of basic skills and subskills in reading, spelling, writing, and mathematics.

Reading. (Also see Chapter 29.3 .) Reading disabilities, also termed dyslexia, may stem from many neurodevelopmental factors. Most commonly, language dysfunctions are present in children with significant reading delays. Initially, such children are likely to reveal *poor phonologic awareness,* as observed in their difficulty appreciating and manipulating language sounds (see earlier). They may then have debilitating problems in forming associations in memory between English language sounds and combinations of letters. This gap results in deficiencies at the level of decoding individual words. Affected children may be slow to acquire a *sight vocabulary* (a repertoire of words they can identify instantly). When decoding skills are delayed or overly laborious, reading comprehension is subsequently seriously compromised. Students with visual-spatial dysfunctions may also have trouble learning to read, but this is a relatively rare cause of reading difficulty. Children with weaknesses of temporal-sequential ordering or active working memory may experience difficulty in breaking down words into their component sounds (phonemes) and reblending them into correct sequences. Memory difficulties can cause problems with reading recall and summarization skill, with associative memory for sounds and symbols, and with the acquisition of vocabulary. Some youngsters with higher-order cognitive deficiencies experience trouble in understanding what they read because they lack a strong grasp of the concepts in a text.

Children with reading difficulties commonly avoid reading. Thus, it is not unusual for a child whose reading is deficient to superimpose on this problem a lack of reading practice. Consequently, a delay in reading proficiency becomes increasingly pronounced over time.

Spelling. Impairments in spelling ability take various forms. Those with language disorders may have difficulty in applying a knowledge of phonology to spelling. They may overuse their visual (configurational) sense of words, and thus their attempts at spelling are phonetically poor approximations yet visually comparable to the actual word (e.g., faght for fight). Other youngsters seem to have the opposite problem, trouble with revisualization or the recall of word configurations. When their phonologic abilities are adequate, their spelling efforts are often phonetically correct but visually far afield (e.g., fite for fight). Some children lack a sense of the *morphology* of language, the sense that certain letter combinations impart certain meanings within words. They may be insensitive to suffixes, prefixes, and word roots. This can be reflected in their spelling patterns. For example, a child may spell the word *played* as *plade.*

Children with certain memory disorders can spell words adequately during a spelling bee or on a spelling list, but they misspell the same words when writing a paragraph. They appear to have a memory problem that leads to difficulty in sustaining several different operations simultaneously.

Some students commit *mixed spelling errors,* many of which are orthographically illegal (i.e., they deploy letter combinations never found in English). Such children have the worst prognoses with regard to spelling proficiency. Overall, the analysis of a child's spelling errors can provide valuable insights into the nature of his or her overall neurodevelopmental profile.

Writing. As children proceed through school, demands for large amounts of well-organized written output increase. Writing difficulties have been classified as Disorder of Written Expression or *dysgraphia*. In many cases, writing is laborious because of an underlying graphomotor dysfunction. In such instances, a child's graphomotor fluency does not keep pace with ideation and language production. Thoughts may also be forgotten or underdeveloped during writing because the mechanical effort is so taxing.

Just as students with simultaneous memory deficiencies experience difficulty with spelling in paragraphs, they are also prone to serious problems with writing in general. Their written output is often inconsistent in its legibility, ideation, and use of rules (of punctuation, capitalization, and grammar). Children with sequential ordering problems may have difficulty in organizing their ideas effectively when they write. Those with expressive language dysfunctions may not be able to use language effectively on paper. Students with active working memory dysfunctions have difficulty getting the ideas in a paragraph to cohere because they keep forgetting what they wish to express. Finally, students with attentional dysfunction may find it hard to mobilize and sustain the mental effort, the pacing, and the self-monitoring demands of writing. In fact, writing difficulties are the most frequently encountered academic problems among children with weak attention controls.

Mathematics. Delays in mathematical ability, Mathematics Disorder or Developmental Dyscalculia, can be especially refractory to correction. In one school-based study, it was found that no student who was delayed more than 6 mo in mathematics in 6th grade ever caught up, and a more recent study has shown persistence of severe arithmetic disorder in half of affected preteen children. Factors associated with persistence of difficulties included severity of the disorder and arithmetic problems in siblings of the probands. Thus, significant mathematical weaknesses can become virtually insurmountable, as the subject is so highly cumulative in its structure. Various forms of mathematical disability plague students.

Some children experience mathematics failure because of discrete higher-order cognitive weaknesses. They cannot grasp arithmetic concepts. Good mathematicians are able to deploy both verbal and nonverbal conceptual abilities to understand such concepts as fractions, percentages, equations, and proportion. It may also be hard for them to apply concepts effectively or be systematic in solving word problems or when confronted with practical situations.

Some youngsters show circumscribed memory weaknesses that compromise mathematical ability. Some have trouble in automatizing mathematical facts (such as the multiplication tables). Others have difficulty in recalling appropriate procedural sequences or *algorithms* (such as the steps involved in solving a long division problem). Still others have weak active working memory; thus, when they focus on one portion of a mathematical problem, they are likely to forget other components of the same problem.

Some students with language dysfunctions have difficulty in mathematics because they have trouble understanding their teachers' verbal explanations of quantitative concepts and operations. Such students are likely to experience frustration in solving word problems and in processing the vast network of technical vocabulary in this subject area. Many students with attention deficits falter in mathematics classes because they are poor at focusing on fine detail (such as operational signs). They may take an impulsive approach to mathematical problem solving and engage in little or no self-monitoring. Consequently, they commit frequent careless errors. Mathematics involves a degree of visualization. Children who have difficulty forming

and recalling visual imagery to enhance learning may be at a disadvantage in acquiring mathematical skills. It may be hard, for example, for them to picture geometric shapes or to think about fractions.

It is not unusual for individuals with mathematical disabilities to develop superimposed mathematical phobias. Anxiety over mathematics can be especially disheartening and can aggravate an underlying skill delay.

Content Area Subjects. Children with neurodevelopmental dysfunctions may experience difficulty in a wide range of academic content areas. The sciences may be a special problem, especially because they necessitate the processing of dense verbal material in textbooks and the rapid convergent recall of facts. Social studies courses often entail use of sophisticated language and a mastery of verbal abstract concepts (e.g., democracy, liberalism, and taxation with representation). Students with higher cognitive weaknesses may not grasp such concepts.

Foreign language learning can be a serious problem for students with language disorders or memory gaps. In particular, those with even mild trouble with phonologic awareness, semantics, or syntax in their first language may have serious problems adding a second language. Some adolescents require foreign language waivers to graduate from high school and enter college. Younger children with learning problems often need to postpone foreign language learning until well into their high school years.

Some students harbor incapacitating *organizational problems* that adversely affect performance in content area subjects. They often lack effective learning strategies. Some are too impulsive to make use of techniques to facilitate studying and work output. Others struggle because they are unable to maintain a systematized notebook, keep track of assignments, get to places on time, meet deadlines, find things, organize a locker, and remember what books to take home from school. Many disorganized students also have trouble studying for tests. They do not seem to know how and what to study and for how long. They frequently lack self-testing skills.

NONACADEMIC IMPACTS.

Neurodevelopmental dysfunctions commonly exert impacts that extend far beyond school. Some nonacademic impacts are closely related to the dysfunctions themselves, whereas other sequelae are secondary to persistent failure and frustration. The impulsivity and lack of effective self-monitoring of children with attention deficits may lead to unacceptable actions that were unintentional. In some cases, children with neurodevelopmental dysfunctions have excessive performance anxiety or clinical depression. Sadness, self-deprecatory comments, declining self-esteem, chronic fatigue, loss of interests, and even suicidal ideation may ensue. Some children lose motivation. They tend to give up and exhibit *learned helplessness,* a sense that they have no personal control over their destinies. Therefore, they feel no need to exert effort. This perspective ultimately can promote depression, pessimism, and a loss of ambition.

Diagnosis (Assessment).

A child who is functioning poorly during the school years requires a careful multidisciplinary evaluation. An optimal evaluation team should consist of a pediatrician, a psychologist or psychiatrist, and a psychoeducational specialist (sometimes called an educational diagnostician). The latter is a clinician (usually a special educator or educational psychologist) who can undertake a detailed analysis of academic skills and subskills. Other professionals should become involved, as needed in individual cases, such as a speech and language pathologist, an occupational therapist, a neurologist, and a social worker.

Many children undergo evaluations in school. Such assessments are guaranteed in the United States under Public Law 101–476, the Individuals with Disabilities Education Act (IDEA). In addition, children found to have attentional dysfunction and

other disorders may qualify for educational accommodations under Section 504 of the Rehabilitation Act of 1973.

Multidisciplinary evaluations conducted in schools are usually very helpful, but they are susceptible to biases and conflicts of interest. School budgeting constraints or lack of personnel may also affect the quality of evaluations and the extent of recommended services. Because of such limitations, demand for independent evaluations and for second opinions outside of the school setting is growing. Many pediatricians become involved in such outside assessments.

Pediatricians can be helpful in gathering and organizing data relating to a child with neurodevelopmental dysfunctions. They can obtain such data through the use of questionnaires completed by the parents, the school, and (if old enough) the child. These questionnaires can provide up-to-date information about behavioral adjustment, patterns of academic performance, and traits associated with specific developmental dysfunctions. In addition, questionnaires can elicit relevant data about a child's health history, family background, and demographic variables relevant to a child's learning difficulty. The ANSER System Questionnaires have been developed for this purpose. Standardized behavioral checklists also can aid in evaluation. Among these are the Child Behavior Checklist (CBCL) and the Behavior Assessment System for Children (BASC).

Evaluation of a child with suspected neurodevelopmental dysfunctions should include complete physical, neurologic, and sensory examinations to rule out underlying or associated conditions that could be exacerbating learning difficulties. It is rare that a specific cause is uncovered. A physician may also perform an extended neurologic and developmental assessment. Available pediatric neurodevelopmental examination instruments that facilitate direct sampling of various neurodevelopmental functions, such as attention, memory, and language, include the Pediatric Early Elementary Examination (PEEX II) and the Pediatric Examination of Educational Readiness at Middle Childhood (PEERAMID II). Examinations of this type also include direct behavioral observations and assessment of minor neurologic indicators (sometimes called *soft signs*). The latter include various associated movements and other phenomena frequently associated with neurodevelopmental dysfunction (see also Chapters 16 , 17 , and 584).

An evaluation commonly includes *intelligence testing* that provides an overall intelligence quotient (IQ). This testing can be useful in relating specific subtest scores to other diagnostic data. Such comparisons can uncover revealing patterns suggestive of specific neurodevelopmental dysfunctions.

Psychoeducational tests yield relevant data, especially when such assessments include careful analyses that pinpoint where breakdowns are occurring in the processes of reading, spelling, writing, and mathematics. A psychoeducational specialist, making use of input from multiple sources, can help a pediatrician formulate specific recommendations for regular and special educational teachers.

A mental health specialist can be valuable in identifying family-based issues or psychiatric disorders that may be complicating or aggravating neurodevelopmental dysfunctions.

Treatment.

Treatment of children with neurodevelopmental dysfunctions often also needs to be multidisciplinary. Most children require several of the following forms of intervention.

DEMYSTIFICATION.

Many children with neurodevelopmental dysfunctions have little or no understanding of the nature or sources of their difficulties. Once an appropriate descriptive assessment has been performed, it is especially important to explain to children the nature of the dysfunction while at the same time delineating their strengths. This explanation should be provided in nontechnical language, infusing a sense of optimism and communicating a desire to be helpful and supportive in the future.

BYPASS STRATEGIES (ACCOMMODATIONS).

Numerous techniques can enable a child to circumvent neurodevelopmental dysfunctions. Such bypass strategies are ordinarily used in the regular classroom; individual forms of intervention in other settings are aimed at strengthening deficient functions. Examples of bypass strategies include using a calculator while solving mathematical problems, writing essays with a word processor, presenting oral instead of written reports, solving fewer mathematical problems, seating a child with attention deficits closer to the teacher to minimize distraction, offering visually presented demonstration models of correctly solved mathematical problems, and granting permission for a student to take scholastic aptitude tests untimed. These bypass strategies do not cure neurodevelopmental dysfunctions but minimize their academic and nonacademic effects.

INTERVENTIONS (REMEDIATION OF SKILLS).

Interventions can be used at home and in school to strengthen the weak links in the learning process. Reading specialists, mathematical tutors, and other such professionals can make use of diagnostic data to select techniques that make use of a student's neurodevelopmental strengths in an effort to improve decoding skills, writing ability, or mathematical computation. Remediation need not focus exclusively on specific academic areas. Many students need assistance in acquiring study skills, cognitive strategies, and productive organizational habits.

Remediation may take place in a resource room or learning center at school. To qualify for these services in school, students may need to be labeled or classified as *learning disabled*. To be so designated, testing must document a substantial discrepancy between the child's IQ and his or her academic skill. Unfortunately, some needy students with significant neurodevelopmental dysfunctions do not display such a discrepancy. Fortunately, increasing numbers of schools and regulatory agencies are giving up these arbitrary criteria and providing help to all

children who demonstrate an academic delay.

Interventions that can be implemented at home could include drills to aid the automatization of subskills such as arithmetic facts or letter formations.

DEVELOPMENTAL THERAPIES.

Considerable controversy exists about the efficacy of treatments to enhance weak developmental functions. It has not been convincingly demonstrated that it is possible to improve substantially a child's fine motor skills, memory, problem-solving proficiency, or temporal-sequential ordering abilities. Nevertheless, some forms of developmental therapy are widely accepted. *Speech and language pathologists* commonly offer intervention for youngsters with various forms of language disability. *Occupational therapists* strive to improve the motor skills of certain students with writing problems or gross motor clumsiness.

CURRICULUM MODIFICATIONS.

Many children with neurodevelopmental dysfunctions require alterations in the school curriculum to succeed. This is particularly true as students progress through secondary school. For example, students with memory weaknesses may need to have their courses selected for them so that they do not have an inordinate cumulative memory load in any one semester. The timing of a foreign language, the selection of a mathematical curriculum, and the choice of science courses are critical issues for many of these struggling adolescents.

STRENGTHENING OF STRENGTHS.

Affected children need to have their affinities, potentials, and talents identified clearly and exploited widely. It is as important to strengthen strengths as it is to attempt to remedy deficiencies. Athletic skills, artistic inclinations, creative talents, and mechanical aptitudes are among the potential assets of certain students who are underachieving academically. Parents and school personnel need to create opportunities for such students to build on these assets and to achieve respect and praise for their efforts. These well-developed personal assets can ultimately have implications for transitions into young adulthood, including career or college selection.

INDIVIDUAL AND FAMILY COUNSELING.

When learning difficulties are complicated by family problems or identifiable psychiatric disorders, psychotherapy may be indicated. Clinical psychologists or child psychiatrists may offer long- or short-term therapy. Such intervention may involve the child alone or the entire family. It is essential, however, that the therapist have a firm understanding of the nature of a child's neurodevelopmental dysfunctions.

CONTROVERSIAL THERAPIES.

A variety of treatment methods for neurodevelopmental dysfunctions have been proposed that have no known scientific proof of efficacy. This list includes dietary interventions (vitamins, fatty acids, or elimination of food additives or potential allergens), neuromotor programs or medications to address vestibular dysfunction, eye exercises, filters, tinted lenses, biofeedback, and other technologic devices. Parents should be cautioned against expending the excessive amounts of time and financial resources usually demanded by these remedies. In many cases it is difficult to distinguish the nonspecific beneficial impacts of increased support and attention paid to the child from the supposed target effects of the intervention.

MEDICATION.

Certain psychopharmacologic agents may be especially helpful in lessening the toll of neurodevelopmental dysfunctions (see Chapters 28 and 29.2). Most commonly, stimulant medications are used in the treatment of children with attention deficits. They are never a panacea because most youngsters with attention deficits have other associated dysfunctions (such as language disorders, memory problems, motor weaknesses, or social skill deficits). Nevertheless, medications such as methylphenidate (Ritalin or Concerta and Metadate sustained action formulations) and dextroamphetamine (Dexedrine or Adderall) can be important adjuncts to treatment because they seem to help some youngsters focus more selectively and control their impulsivity. Stimulant medication, its indications, administration, and complications are described in Chapter 29.2 . When depression or excessive anxiety is a significant component of the clinical picture, antidepressants or antianxiety drugs may be helpful (Chapters 22 and 23). Other drugs may improve behavioral control (Chapter 28). Children receiving medication need regular follow-up visits that include a history to check for side effects, a review of current behavioral checklists, a complete physical examination, and appropriate modifications of medication dose. Periodic trials off medication are recommended, to establish whether the medication is still necessary.

THE ROLE OF THE PEDIATRICIAN

Pediatricians should play a central role in assisting children with neurodevelopmental dysfunctions. Their longitudinal contact with the child and family enables them to critically assess medical, family, and developmental history to identify children at risk. They are well positioned to assess whether early perturbations in developmental progression represent normal variations or warning signs of future learning problems. Regular contact over the course of the school years provides the opportunity to identify and participate in the assessment of learning difficulties, coordinate management, and function as a counselor and advocate.

Key elements are necessary in order for the pediatrician to effectively fill these roles. The pediatrician needs to maintain an accurate base of knowledge regarding the clinical manifestations of neurodevelopmental dysfunction, methods of diagnosis and management, the resources available within the school system as well as other clinicians in the region, and the public laws that entitle eligible students to modifications, accommodations, and interventions. A system of screening and surveillance

should be incorporated into routine office visits to promote early identification of learning difficulties. This could include standard screening questionnaires or direct questioning of parents regarding any possible concerns about their child's school performance. If problems emerge, the pediatrician should rule out medical causes and can participate in the assessment process as described earlier. He or she can advise and assist parents in obtaining necessary evaluations through the school or by referral to independent clinicians. Assistance should be provided in the interpretation of the findings, ensuring appropriate demystification of the child and coordinating care if other medical specialists are involved. Pediatricians can also play a critical role in those children who might require medication as a component of a management plan.

Drawing on their relationship with the child and parents, pediatricians can provide helpful advice and counseling in dealing with the stresses associated with learning challenges such as confrontations related to homework, and ensuring students are afforded regular opportunities to pursue their affinities. Children with neurodevelopmental dysfunctions require informed advocacy. They need to have their rights upheld in school and in the community. Pediatricians can be especially helpful in advocating for children in school. Some children, for example, are devastated by being held back in a grade, and the likelihood of benefit may be minimal. A physician may need to represent the rights of the child in opposing such grade retention and other sources of public humiliation. A physician may also need to argue strongly for a child to receive services in school or to benefit from modifications in the curriculum. Pediatricians can also perform advocacy by becoming vocal citizens of their communities. In serving on a school board, for example, a physician can exert a major influence on local policy and on the allocation of resources to school children with special educational needs.

Longitudinal Case Management.

All children with neurodevelopmental dysfunctions can benefit from the support and guidance of a case manager or mentor, a professional who can offer advice in a continuing manner and be available to monitor function through the years. Pediatricians may be the ideal professionals to assume this responsibility. With time, new questions inevitably emerge as a child's neurodevelopmental dysfunctions evolve and academic expectations undergo progressive changes. Because children with neurodevelopmental dysfunctions represent an extremely heterogeneous group, no two children require the same management plan, nor is it possible to predict with certainty at age 7 the needs of a youngster when he or she is 14 yr old. Consequently, affected children and their families require vigilant follow-up and individualized objective advice throughout their academic careers.

29.2 Attention-Deficit/Hyperactivity Disorder

Mark D. Simms

Attention-deficit/hyperactivity disorder (ADHD) is the most common neurobehavioral disorder of childhood, one of the most prevalent chronic health conditions affecting school-aged children, and the most extensively studied mental disorder of childhood. According to the fourth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual* (DSM-IV), ADHD is characterized by inattention, including increased distractibility and difficulty sustaining attention; poor impulse control and decreased self-inhibitory capacity; and motor overactivity and motor restlessness (Table 29–1). These symptoms are pervasive and interfere with the individual's ability to function under normal circumstances. DSM-IV identifies three types of ADHD: predominantly hyperactive-impulsive symptoms, predominantly inattentive symptoms, and combined type. Affected children commonly experience problems with academic underachievement, interpersonal relationships with family members and peers, and low self-esteem. ADHD frequently co-occurs with other emotional, behavioral, language and learning disorders (Chapter 29.1). Fortunately, a variety of safe and effective psychosocial, behavioral, and pharmacologic therapies are available to treat the disorder's major symptoms.

Etiology.

ADHD is a heterogeneous condition for which no single cause has been identified. However, evidence suggests that genetic and environmental factors play a significant role during fetal and postnatal development in the emergence of ADHD during early childhood. Both morphologic and functional brain differences have been identified, including a moderate reduction in the size of the corpus callosum, basal ganglia, and frontal lobes, and hypoperfusion of the frontal-striatal dopamine pathways. Furthermore, ADHD commonly occurs following damage to the CNS (e.g., prematurity or traumatic brain injury), toxic exposure (e.g., fetal alcohol syndrome or lead poisoning), maldevelopment (e.g., mental retardation syndromes), and sequelae of infectious processes affecting the CNS. ADHD also occurs in otherwise physically healthy children. Twin and family studies suggest a strong genetic component to ADHD, and molecular genetic studies have identified abnormalities in the dopamine transporter gene, the D4 receptor gene, and human thyroid receptor beta gene.

Epidemiology.

Although the DSM-IV estimates the prevalence to be between 3% and 5% among school-aged children, community samples of school-aged children suggest a prevalence rate ranging from 4% to 12%. The condition is approximately 3 to 4 times more common in males (9.2%) than females (2.9%); however, the inattentive subtype is the most common in females. Environmental factors, such as psychosocial stressors, parenting difficulties, and classroom factors may exacerbate ADHD but do not cause the syndrome. Contrary to common opinion, epidemiologic studies suggest that ADHD is underdiagnosed in the population at large, and children with the disorder are often undertreated with medications.

Clinical Manifestations.

DSM-IV criteria were developed in field trials conducted mainly with children 5 to 12 yr of age. These criteria emphasize several factors. Behaviors must be statistically abnormal for the child's age and developmental level, must begin before the age of 7 yr, and must be present for at least 6 mo. Symptoms must also be pervasive in nature (present in at least two or more settings) and impair the child's ability to function normally. Finally, symptoms must not be secondary to another disorder.

TABLE 29.2-1 -- DSM-IV Diagnostic Criteria for ADHD

A. Either 1 or 2
   1. Six (or more) of the following symptoms of inattention have persisted for at least 6 mo to a degree that is maladaptive and inconsistent with development level:
      Inattention
      a. Often fails to give close attention to details or makes careless mistakes in school work, work, or other activities
      b. Often has difficulty sustaining attention in tasks or play activities
      c. Often does not seem to listen when spoken to directly
      d. Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions)
      e. Often has difficulty organizing tasks and activities
      f. Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (such as schoolwork or homework)
      g. Often loses things necessary for tasks or activities (e.g., toys, school assignments, pencils, books, or tools)
      h. Is often easily distracted by extraneous stimuli
      i. Is often forgetful in daily activities
   2. Six (or more) of the following symptoms of hyperactivity-impulsivity have persisted for at least 6 mo to a degree that is maladaptive and inconsistent with developmental level:
      Hyperactivity
      a. Often fidgets with hands or feet or squirms in seat
      b. Often leaves seat in classroom or in other situations in which remaining seated is expected
      c. Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)
      d. Often has difficulty playing or engaging in leisure activities quietly
      e. Is often "on the go" or often acts as if "driven by a motor"

seated is expected

c. Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness)
d. Often has difficulty playing or engaging in leisure activities quietly
e. Is often “on the go” or often acts as if “driven by a motor”
f. Often talks excessively

Impulsivity

g. Often blurts out answers before questions have been completed
h. Often has difficulty awaiting turn
i. Often interrupts or intrudes on others (e.g., butts into conversations or games)

B. Some hyperactive-impulsive or inattentive symptoms that caused impairment were present before 7 yr of age.
C. Some impairment from the symptoms is present in 2 or more settings (e.g., at school [or work] or at home).
D. There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning.
E. The symptoms do not occur exclusively during the course of a pervasive developmental disorder, schizophrenia, or other psychotic disorder and are not better accounted for by another mental disorder (e.g., mood disorder, anxiety disorder, dissociative disorder, or personality disorder).

Code based on type:
314.01 Attention-Deficit/Hyperactivity Disorder, Combined Type: if both Criteria A1 and A2 are met for the past 6 months.
314.00 Attention-Deficit/Hyperactivity Disorder, Predominantly Inattentive type: if Criterion A1 is met but Criterion A2 is not met for the past 6 months.
314.01 Attention-Deficit/Hyperactivity Disorder, Predominantly Hyperactive-Impulsive Type: if Criterion A2 is met but Criterion A1 is not met for the past 6 months.

With increasing age, clinical manifestations may change from predominantly motor restlessness, aggressive, and disruptive behavior in preschool children to disorganized, distractible, and inattentive symptoms in older adolescents and adults. In particular, ADHD is more difficult to diagnose in preschool children, who normally tend to be active and restless. The disorder is also difficult to identify in children with cognitive disabilities, who often act in an immature fashion and whose intentions may be difficult to judge.

Diagnosis.

Diagnoses of ADHD are made primarily on clinical grounds after a thorough evaluation whose components include behavior rating scales, the clinical interview, physical examination, and neuropsychologic evaluation.

BEHAVIOR RATING SCALES.

Several standardized behavior rating scales are widely available and perform well in discriminating between children with ADHD and controls (e.g., Conner's Rating Scale; ADHD Index; Swanson, Nolan, and Pelham Checklist [SNAP]; ADD-H: Comprehensive Teacher Rating Scale [AcTERS]). Other broad-band checklists, such as the Achenbach Child Behavior Checklist (CBCL) are useful in screening for co-occurring problems in areas other than ADHD (e.g., anxiety, depression, conduct problems, etc.). It is important to gather information from a variety of sources—typically parents, teachers, and, when appropriate, other caretakers—to determine pervasiveness of the symptoms. These scales are useful in establishing the magnitude and pervasiveness of the symptoms but are not sufficient alone to make a diagnosis of ADHD.

CLINICAL INTERVIEW.

A major goal of the clinical interview is exploration of whether symptoms might be the result of other conditions that mimic ADHD. Review of the child's health, development, and social and family history should emphasize factors that might affect the development or integrity of the CNS, or reveal the presence of chronic illness, sensory impairments, or medication use that might affect the child's functioning. Disruptive social factors, such as family discord, situational stresses, abuse, or neglect may result in hyperactive or anxious behaviors. Finally, a family history of first-degree relatives with ADHD, mood or anxiety disorders, learning disability, antisocial disorder, or alcohol or substance abuse may indicate increased risk for ADHD and/or co-morbid conditions.

PHYSICAL EXAMINATION.

No medical screening or laboratory tests are specific to ADHD. However, careful examination may reveal the presence of chronic illnesses, sensory impairments, or genetic/birth defect syndromes that may contribute to behavioral and learning difficulties. The presence of hypertension, motor tics, ataxia, or thyroid disorder may be contraindications for use of stimulant medications to treat ADHD symptoms and should prompt further diagnostic evaluations. Fine motor coordination delays and other “soft signs” are common but are not sufficiently specific to contribute to a diagnosis of ADHD. It is important to note that behavior in a highly structured or novel setting may not reflect typical behavior at home or school. Reliance on observed behavior in a physician's office may result in incorrect diagnosis.

NEUROPSYCHOLOGIC EXAMINATION.

Standardized tests of general intelligence and educational achievement may indicate the presence of mental retardation or specific learning disabilities. Incompatibility between classroom expectations and the child's ability may result in inattentive or inappropriate behaviors. Tests of sustained attention—continuous

performance tests—can help corroborate a diagnosis of ADHD but are not adequate by themselves to confirm or deny the diagnosis.

Differential Diagnosis.

Chronic illnesses affect up to 20% of children in the United States and may impair children's attention and school performance (e.g., migraine headaches, absence seizures, asthma and allergies, hematologic disorders, juvenile diabetes, childhood cancer, etc.), either because of the disease itself or medications used to treat or control the underlying illness (e.g., medications for asthma, steroids, anticonvulsants, antihistamines). In older children and adolescents, substance abuse may result in declining school performance and inattentive behavior.

Sleep disorders, including those secondary to chronic upper airway obstruction from enlarged tonsils and adenoids, frequently result in behavioral and emotional symptoms. Conversely, behavioral and emotional disorders may cause disrupted sleep patterns.

Depression and anxiety disorders may present many of the same symptoms as ADHD (e.g., inattention, restlessness, inability to focus and concentrate on work, poor organization, forgetfulness) and may be present as co-morbid conditions. Obsessive-compulsive disorder may mimic ADHD, particularly when recurrent and persistent thoughts, impulses, or images are intrusive and interfere with normal daily activities.

Adjustment disorders secondary to major life stresses (e.g., death of a close family member, parental divorce, family violence, parental substance abuse, a move, etc.) or parent-child relationship disorders involving conflicts over discipline, overt child abuse and/or neglect, or overprotection, may result in symptoms similar to ADHD.

Finally, although ADHD is thought to be due to primary impairment of attention, impulse control, and motor activity, other disorders are frequently present as co-morbid conditions: oppositional defiant disorder or conduct disorder (35%), depression and mood disorders (18%), anxiety disorder (25%), and learning disorders (10–25%).

Treatment.

Psychosocial interventions, behavior management training, and medication are effective in treating the various components of ADHD. The National Institute of Mental Health Collaborative Multisite Multimodal Treatment Study of Children with Attention-Deficit/Hyperactivity Disorder (MTA study) demonstrated the effectiveness of stimulant medication in treating core symptoms of ADHD, whereas psychosocial interventions and behavior management training were effective in treating many co-morbid disorders frequently seen in children with ADHD.

PSYCHOSOCIAL INTERVENTIONS.

Once the diagnosis has been established, parent(s) and child should be educated about the ways in which ADHD can affect learning, behavior, self-esteem, social skills, and family function. Goals should be set to improve the child's relationships with parents, siblings, teachers, and peers; decrease disruptive behaviors; increase independence in completing homework; and improve self-esteem. Behavior therapy should include a broad plan for modifying the physical and social environment, as well as the child's behaviors. For example, school and home settings may be adjusted to accommodate the child's learning style and decrease distractions.

BEHAVIOR MANAGEMENT TRAINING.

Training may consist of 8–12 weekly individual or group sessions. Parents learn principles of behavior management with emphasis on consistency, while children work on improving peer relationships and self-esteem. Specific “target” behaviors are identified that impair the child's daily life functions (e.g., violating home or school rules, disruptive behavior, not completing homework assignments, etc.). Next, parents and teachers must implement specific techniques of providing rewards to the child for demonstrating the desired behavior (positive reinforcement) or consequences for failure to meet the goals (negative reinforcement). Family and individual psychotherapy may be necessary in complex situations or to address overt mental health conditions such as depression, anxiety, social withdrawal, school phobia, etc. Psychologists, school personnel, community mental health therapists, or primary care clinicians can provide behavior therapy; however, many clinicians prefer to refer families to community providers because behavior therapy is time-consuming and often requires specific training and skills. National organizations, such as CHADD (Children with Attention Deficit Disorders) and ADDA (Attention Deficit Disorders Association) may also provide valuable support to families and children.

MEDICATION.

Stimulants are the most effective psychotropic agents in treating ADHD, but several other types of medications should be considered in management of complex cases. Stimulants have been used for over 60 yr and have an excellent safety record. Research shows that stimulant medications are effective in ameliorating core symptoms of inattention, impulsivity, and hyperactivity. In addition, improvements are seen in noncompliant behaviors, impulsive aggression, social interactions with peers and family members, and academic productivity and accuracy. In contrast, stimulants are not likely to improve reading skills, academic achievement, or antisocial behaviors.

The two main classes of stimulants are methylphenidate and its derivatives (Ritalin, Concerta, Metadate CD, and Methylin) and amphetamine and its derivatives (Dexedrine and Adderall). Both classes are available in short, intermediate, and long-acting forms. All stimulant forms are equally effective, but individual children may respond differently to one or another medication and clinicians may choose one over another to tailor the pharmacologic effect to meet the child's lifestyle needs. When the stimulants are used sequentially, approximately 80% of children will respond favorably to one of them with satisfactory relief of major symptoms of ADHD.

Stimulants have few contraindications and adverse effects are usually predictable and generally mild. Common short-term side effects include loss of appetite, initial weight loss, abdominal discomfort, dysphoria, and difficulty sleeping. A slight increase in heart rate may also be seen. Less often, tics may become evident in children who start stimulant medications. These adverse symptoms usually remit when the dosage is lowered, or when an alternative stimulant preparation or another class of medication is used. Other agents, such as tricyclic antidepressants (imipramine and desipramine) and buproprion (Wellbutrin) are considered

second-line agents that have been shown to be effective in treating ADHD, particularly in the presence of co-morbid depression. Alpha-2 adrenergic blocker agents, such as clonidine (Catapres) and guanfacine (Tenex), are also effective and often used alone or in combination with stimulants. See Table 29–2 for doses of stimulants and antidepressants.

Contrary to popular misconceptions, long-term use of stimulants, as recommended, does not result in addiction (i.e., there is no development of tolerance, craving, or withdrawal) and is unlikely to lead individuals with ADHD to abuse drugs. Evidence suggests that adolescents and young adults who take prescribed stimulants for ADHD have a much lower incidence of illicit substance and alcohol abuse than those who do not receive appropriate treatment. Similarly, stimulants do not result in aggressive or assaultive behavior, do not increase the risk of seizures, are not a cause of Tourette syndrome, and do not exacerbate anxiety disorders.

Prognosis.

In at least 80% of affected children, symptoms of ADHD persist into adolescence and adulthood. With increasing

TABLE 29.2-2 -- Medications Used in the Treatment of Attention-Deficit/Hyperactivity Disorder

Generic Class (Brand Name)	Daily Dosage Schedule	Duration	Prescribing Schedule
Stimulants (First-Line Treatment)			
Methylphenidate			
Short-acting (Ritalin, Methylin)	Twice a day (bid) to 3 times a day (tid)	3–5?hr	5–20?mg bid to tid
Intermediate-acting (Ritalin SR, Metadate ER, Methylin ER)	Once a day (qd) to bid	3–8?hr	20–40?mg qd or 40?mg in the morning and 20 early afternoon
Long-acting (Concerta, Metadate CD, Ritalin LA*)	qd	8–12?hr	18–72?mg qd
Amphetamine			
Short-acting (Dexedrine, Dextrostat)	bid to tid	4–6?hr	5–15?mg bid or 5–10?mg tid
Intermediate-acting (Adderall, Dexedrine spansule)	qd to bid	6–8?hr	5–30?mg qd or 5–15?mg bid
Long-acting (Adderall-XR)	qd		10–30?mg qd
Antidepressants (Second-Line Treatment)			
Tricyclics (TCAs)	bid to tid		2–5?mg/kg/day†
Imipramine, Desipramine			
Bupropion			
(Wellbutrin)	qd to tid		50–100?mg tid
(Wellbutrin SR)	bid		100–150?mg bid

age, hyperactivity tends to decrease while inattention, impulsivity, disorganization, and relationship difficulties often persist and become more prominent. If not properly identified and treated, affected individuals across the age span are at risk for a wide range of unfavorable health and psychosocial outcomes, including accidental injuries, educational underachievement, employment difficulties, risky sexual behavior, and criminal activity. However, evidence suggests that with a combination of medication and psychosocial and behavioral interventions, most children's symptoms are significantly ameliorated. **REFERENCES**

29.3 Specific Reading Disability (Dyslexia)

G. Reid Lyon
Sally E. Shaywitz
Bennett A. Shaywitz

Dyslexia is characterized by an unexpected difficulty in reading in children and adults who otherwise possess the intelligence, motivation, and opportunities to learn considered necessary for accurate and fluent reading. Dyslexia is the most common and most comprehensively studied of the learning disabilities (LD), affecting at least 80% of children identified as manifesting LD. When asked to read aloud, most children and adults with dyslexia display a labored approach to decoding and recognizing single words, an approach characterized by hesitations, mispronunciations, and repeated attempts to sound out unfamiliar words. In contrast to the difficulties they experience in decoding single words, individuals with dyslexia have the vocabulary, syntax, and other higher level abilities involved in comprehension.

Etiology.

At a cognitive-linguistic level, dyslexia reflects deficits within a specific component of the language system, the phonologic module, which is engaged in processing the sounds of speech. As predicted by this model, dyslexic individuals have difficulty developing an awareness that words, both spoken and written, can be segmented into smaller elemental units of sound—an essential ability given that reading an alphabetic language (i.e., English) requires that the reader map or link printed symbols to sound. Abundant evidence shows that the linguistic abilities related to learning to read involve phonology, with deficits in phonologic awareness best predicting dyslexia. Theories of dyslexia that implicate the visual system or deficits in the temporal processing of auditory and visual stimuli have not been sufficiently substantiated by research.

Dyslexia is both familial and heritable. Family history is one of the most important risk factors; about half of children who have a parent with dyslexia as well as half of the siblings of dyslexics and half of the parents of dyslexics may have the disorder. Linkage studies implicate loci on chromosomes 1, 2, 6, and 15 for the transmission of phonologic awareness deficits and subsequent reading problems. The specific mechanisms by which genetic factors predispose someone to dyslexia are not clear.

A range of neurobiologic investigations using postmortem brain specimens, brain morphometry, and diffusion tensor magnetic resonance imaging suggests that there are differences in the left temporo-parieto-occipital brain regions between dyslexic and nonimpaired readers. Converging evidence using functional brain imaging in both children with dyslexia and adult dyslexic readers shows a failure of left hemisphere posterior brain systems to function properly during reading with increased activation in frontal regions. These data suggest that rather than the smoothly functioning and integrated reading systems observed in nonimpaired children, disruption of the posterior reading systems results in dyslexic children attempting to compensate by shifting to other, ancillary systems, for example, anterior sites such as the inferior frontal gyrus and right hemisphere sites. These data suggest that in dyslexic readers disruption of posterior reading systems underlies the failure of skilled reading to develop, while a shift to ancillary systems supports accurate, but not automatic, word reading.

Epidemiology.

Dyslexia may be the most common neurobehavioral disorder affecting children, with prevalence rates ranging from 5–10% in clinic- and school-identified samples to 17.5% in unselected population-based samples. Like hypertension and obesity, dyslexia fits a dimensional model in which reading ability and disability occur along a continuum, with dyslexia representing the lower tail of a normal distribution of reading ability. In contrast to traditional assumptions, several studies indicate similar numbers of affected males and females. Both prospective and retrospective longitudinal studies indicate dyslexia is a persistent, chronic condition rather than a transient developmental lag. Over time, dyslexic and poor readers maintain their relative positions along the distribution of reading ability. However, approaches using focused, early, and intensive intervention provide promise that these trends can be modified.

Clinical Manifestations.

Difficulties in decoding and word recognition may vary according to age and developmental level. However, the cardinal signs of dyslexia observed in school-aged children and adults are an inaccurate and labored approach to decoding, word recognition, and text reading. Listening comprehension is typically robust. In several studies, older children have been found to improve reading accuracy over time, albeit without commensurate gains in reading fluency; they remain slow readers. Difficulties in spelling typically reflect the phonologically based difficulties observed in oral reading. A parental history frequently identifies early subtle language difficulties in dyslexic children. Many children identified as dyslexic during the primary grades displayed difficulties playing rhyming games and learning the names for letters and numbers during the preschool and kindergarten years. Indeed, recent longitudinal studies demonstrate that kindergarten assessments of these language skills are highly predictive of later reading skill. Parents also frequently report that although their child relishes the opportunity to be read to, reading aloud to the parent or reading independently is resisted. Dyslexia may co-occur with attention-deficit/hyperactivity disorder (ADHD). Although this co-morbidity has been documented in both referred samples (40% co-morbidity) and nonreferred samples (15% co-morbidity), the two disorders are distinct and separable.

Diagnosis.

At all ages, dyslexia is a clinical diagnosis. The clinician seeks to determine through history, observation, and psychometric assessment if there are (1) unexpected difficulties in reading (i.e., difficulties in reading that are unexpected for the person's cognitive capacity as shown by his or her age, intelligence, level of education, or professional status) and (2) associated linguistic problems at the level of phonologic processing. There is no single test score that is pathognomonic of dyslexia. The diagnosis should reflect a thoughtful synthesis of all the clinical data available. Dyslexia is distinguished from other disorders that may prominently feature reading difficulties by the unique, circumscribed nature of the phonologic deficit, one not intruding into other linguistic or cognitive domains. Family history, teacher/classroom observation, and tests of language (particularly phonology), reading, and spelling represent a core assessment for the diagnosis of dyslexia in children; additional tests of intellectual ability, attention, memory, general language skills, and mathematics may be administered as part of a more comprehensive evaluation of cognitive, linguistic, and academic function.

Treatment.

The management of dyslexia demands a life-span perspective; early on, the focus is on remediation of the reading problem. Newer knowledge of the importance of early language and phonologic skills may lead to the prevention of significant reading problems, even in predisposed children. As a child matures and enters the more time-demanding setting of secondary school, the emphasis shifts to the important role of providing accommodations. Until very recently school reading intervention was not based on rigorous scientific evidence; overall, it was too little, too general, and too unsystematic. Based on the work of the National Reading Panel, evidence-based reading intervention programs have now been identified. Effective intervention programs are balanced; they provide systematic instruction in phonemic awareness, phonics, fluency, vocabulary, and comprehension strategies and provide ample opportunities for writing, reading, and discussing literature. Taking each component of the reading process in turn, effective interventions improve phonemic awareness (PA): the ability to focus on and manipulate phonemes (speech sounds) in *spoken* syllables and words. The elements found to be most effective in enhancing PA, reading, and spelling skills include teaching children to manipulate phonemes with letters; focusing the instruction on one or two types of phoneme manipulations rather than multiple types; teaching children in small groups; and providing *systematic, explicit* instruction rather than incidental instruction in PA. Providing instruction in PA is necessary but not sufficient to teach children to read. Effective intervention programs include teaching phonics, that is, making sure that the beginning reader understands how letters are linked to sounds (phonemes) to form letter-sound correspondences and spelling patterns. Often overlooked, and critical to effectively teaching phonics, is to make sure that the instruction is explicit and systematic; phonics instruction enhances children's success in learning to read and systematic phonics instruction is more effective than instruction that teaches little or no phonics or teaches phonics haphazardly or in a “by-the-way” approach. The Report of the National Reading Panel also provides information on teaching fluency, vocabulary, and comprehension strategies. The treatment of dyslexia in students in high school, college, and graduate school is typically based on accommodation

rather than remediation. College students with a childhood history of dyslexia require extra time in reading and writing assignments as well as examinations. Many adolescent and adult students have been able to improve their reading accuracy, though without commensurate gains in reading speed. Other helpful accommodations include the use of laptop computers with spelling checkers, tape recorders in the classroom, recorded books, access to lecture notes, tutorial services, alternatives to multiple choice tests, and a separate quiet room for taking tests.

Part 4 - Social Issues

Chapter 30 - Adoption

Mark D. Simms
Madelyn Freundlich

Adoption is a social, emotional, and legal process that provides a new family for children when the birth family is unable or unwilling to parent. Approximately 1 million children in this country are adopted; 2–4% of all American families have adopted. In 1992, the last year for which total adoption statistics are available, 127,441 children of all races and nationalities were adopted in the United States. Of these, 42% were stepparent or relative adoptions, 15.5% were children in foster care, and 5% were children from other countries adopted by United States families. Private agencies or independent practitioners, such as lawyers, handled approximately one third of adoptions.

Over the past several years, there have been significant increases in the number of children adopted from the *foster care system* in this country as well as in the number of children adopted from other countries by United States families. Changes in federal law in 1997 required that children in foster care who could not be safely returned to their families within a reasonable period of time be placed with adoptive families. With the implementation of the Adoption and Safe Families Act, the number of adoptions of children in foster care began to grow from what previously had been about 18,000 adoptions of children in foster care each year. In 1997, approximately 31,000 children were adopted; by 1999, approximately 46,000 children in foster care had been adopted. At the same time, the number of children in foster care who need adoptive families has grown dramatically. In March 2000, an estimated 134,000 children in foster care were waiting to be adopted. Many children in foster care who are waiting to be adopted have “special needs” because they are of school age, part of a sibling group, or members of ethnic or racial minority groups, or because they

have physical, emotional, or developmental problems (including HIV infection, AIDS, or prenatal exposure to illicit substances). Federal adoption subsidies, tax credits, special minority recruitment efforts, increased postplacement services, and approval of adoptions by "nontraditional" families (particularly single adults and older couples) are aimed at increasing the adoption opportunities for these children.

International adoptions have increased substantially in the past decade. In 2000, United States families adopted 18,537 children from other countries (compared with 7,093 in 1990). China, Russia, South Korea, and Guatemala have become the primary sending countries for children. Most children placed for international adoption have histories of poverty and social hardship in their home countries, and many are adopted from orphanages and other institutional settings. Children who are adopted internationally may be healthy infants and older children, but they also may have "special needs" that are similar to the needs of children in the United States foster care system. Under a new federal law implementing the Hague Convention on Intercountry Adoption, agencies in the United States that arrange international adoptions must make efforts to obtain accurate and complete health histories on children whom families are considering for adoption.

Role of Pediatricians.

Pediatricians can help prospective adoptive parents evaluate the health and developmental history of a child and available background information from birth families in order to assess actual and potential problems or risks that children may have. Adoption agencies increasingly are making efforts to obtain from birth mothers and birth fathers information about their own health and genetic histories and the histories of their children so that this information can be shared with adoptive families. It is likely that more background information will be available in domestic adoptions than in international adoptions. Nevertheless, in international adoptions, pediatricians can assist adoptive families in understanding and evaluating the information that is available about the child's background and current condition (including reviewing any video of the child that has been provided to the family). Assistance in evaluating the child's current status and future health risks should be provided, if possible, before the family travels abroad or the child arrives in the United States. After the child is settled in the new home, pediatricians should encourage adoptive parents to seek a comprehensive assessment of the child's health and development. A significant number of internationally adopted children have acute or chronic medical problems. Routine screening for infectious diseases and disorders of growth and development are recommended for all children arriving in the United States.

Pediatricians also can promote positive adjustment of the child and family by providing guidance and support at all stages of the adoption. Families should be encouraged to speak freely and repeatedly about adoption with the child, beginning in the toddler years and continuing through adolescence. Pediatricians may need to respond to a number of concerns and questions on the part of adoptive parents or adopted adolescents when the adoptee's health and genetic history is incomplete or unknown.

Research shows that most adopted children and families adjust well and lead healthy, productive lives. It is not common that adoptions disrupt. Research, however, shows that disruption rates are higher among children adopted from foster care, which the research associates with their older ages at time of adoption and their histories of multiple placements before their adoptions. As a result of a greater understanding of the needs of families who adopt children from foster care, agencies are placing greater emphasis on the preparation of adoptive parents and ensuring the availability of a full range of postadoption services, including physical health, mental health, and developmental services for their adopted children.

Chapter 31 - Foster Care

Mark D. Simms
Madelyn Freundlich

As of March 2000, there were approximately 588,000 children in state-supported foster care in the United States, compared with 262,000 children in 1982. Over the past 2 decades, efforts to reduce the number of children in foster care have been largely unsuccessful.

Developed as a temporary measure to assist families in crisis, the foster care system became overwhelmed in the 1960s and 1970s as the number of children determined to be abused or neglected and in need of foster care increased dramatically. By the late 1970s, it had become apparent that far too many children were remaining in foster care for extended periods of time without clear plans for their futures. In 1980, the Adoption Assistance and Child Welfare Act (PL 96-272) changed the emphasis of public policy by requiring states to make “reasonable efforts” to prevent children from entering foster care and to reunify children in foster care with their families. The act advanced permanency planning as a process to prevent children from remaining in foster care for indefinite periods of time. It required that children in foster care have clearly defined permanency goals (return home, placement with relatives, adoption) no later than 18 months from the time they entered foster care and that there be periodic court reviews of children's placements and progress toward achieving their permanency goals. Although some progress was realized through the mid-1980s, the drug epidemic that began in the late 1980s set the stage for a new influx of children into foster care. The population of children in foster care has grown steadily since that time in the face of worsening circumstances facing many families (poverty, substance abuse, homelessness, mental health problems). In 1997, the Adoption and Safe Families Act (PL 105-89) was enacted in an effort to prompt more timely permanency planning for children in foster care. Under the new law, a permanency plan must be made for a child in foster care no later than 12 months from the child's entry into care and a petition to terminate parental rights must be filed to free the child for adoption when a child has been in foster care for 15 of the most recent 22 months (with some exceptions). Adoption (see Chapter 30) is now viewed as an important option for children in foster care.

In 1999, there were 3 million reports of child abuse and neglect; of these reports, 868,000 were substantiated for abuse or neglect (see Chapter 35). The vast majority of children in foster care have histories of abuse or neglect. Far fewer children are in care because of the child's own physical or mental health problems or because parents, as a result of a personal or family emergency, voluntarily place their child in foster care. Although foster care has narrowed so that most children and their families can gain access to help only if the child is abused or significantly neglected, new federal programs have been developed to assist families before crises involving child abuse or serious neglect. The Promoting Safe and Stable Families program (under Title IV-B of the Social Security Act), in particular, funds a range of family support and family preservation programs. Although foster care payments under Title IV-E of the Social Security Act continue to far exceed funding for child and family services programs under Title IV-B, greater efforts are being made to address the issues that are associated with child abuse and neglect and the need for children to be placed in foster care: parental substance abuse, domestic abuse, inadequate housing and homelessness, lack of parenting skills, unemployment and underemployment, parental mental and physical health problems, and parental incarceration.

An increasing proportion of children entering foster care are young. Close to half (47%) of the children who entered foster care between October 1999 and March 2000 were younger than 5 yr. Most (42%) were white, but significant percentages were black (29%) and Latino (13%). Children continue to remain in care for significant periods of time, an average of 21 months for children in foster care in March 2000. Importantly, close to half the children in foster care (45%) have been in foster care for 2 or more years.

Children who enter foster care have extraordinarily high rates of medical, developmental, and mental health problems. Most suffer from behavioral and adjustment problems. Nearly 60% of preschoolers are developmentally delayed, and more than half of school-aged children lag behind their peers academically. A disproportionate number of children in foster care have chronic medical conditions (35%), physical growth failure (25%), and congenital abnormalities (15%). Children in foster care have high utilizations rates for all types of care (especially inpatient hospitalization and outpatient mental health services) and, as a group, they incur high health care costs. Both the chances of entering foster care and the likelihood of longer stays in care have been associated with the presence of mental health problems, physical disabilities, and developmental delays. Nonetheless, when children receive needed services, they experience significant improvements in overall health status, stabilization of chronic conditions, and growth and development.

In 1988, the Child Welfare League of America, in collaboration with the American Academy of Pediatrics, published *Standards for the Health Care of Children in Out-of-Home Care* to serve as a blueprint for the effective delivery of services to children in foster care. These standards, in general, have not been implemented. Moreover, despite the availability of comprehensive diagnostic and treatment services under the Medicaid program, known as EPSDT (Early Periodic Screening, Diagnosis, and Treatment), which is mandatory in all states, the majority of children in foster care do not receive these services.

A variety of factors act as barriers to the health care of children in foster care. Most public and private child welfare agencies do not have formal policies or arrangements to provide health care services and, instead, rely on local physicians or health clinics funded by Medicaid. It is often difficult to obtain complete information on the health histories of children who enter foster care because they often have had

erratic contact with various health care providers before they enter foster care, and social workers are not always able to obtain detailed information from biological parents at the time children enter care. Once children enter foster care, there is often a diffusion of responsibility regarding obtaining health care services for children. Foster parents often are given very little information about the health care needs of the children for whom they are caring, but they typically are expected to decide when and where children receive health care services. In some cases, social workers may oversee the health care of children in foster care, but coordination with health care providers is often lacking. Uncertainty as to who may make health care treatment decisions for children may further delay health care or result in the denial of health care services.

Recent federal data indicate that the majority of children in foster care for relatively short periods have only one or two placements while they are in care (81% of the children who are in care for less than 12 mo). For children in care for longer periods of time, however, a much smaller percentage have only one or two placements while they are in care (only 39% of the children who have been in care for 48 mo or more). Changes in caregivers and residences are associated with poorer psychological

and developmental outcomes for children and often mean changes in children's health care providers. At the same time, regardless of whether children's placements change, children's social workers often change (primarily because of high turnover rates) and, as a result, key aspects of health care planning and coordinating may be disrupted.

The health care of poor children, in general, and of children in foster care, in particular, continues to be a key policy issue. The traditional “safety net” previously provided by federal and state programs for economically distressed families (as represented in the past by the Aid to Families with Dependent Children [AFDC] program, Supplemental Security Income [SSI] program, and food stamps) has been substantially modified or replaced by new time-limited, benefit-limited programs. AFDC was replaced by the Temporary Assistance for Needy Families (TANF) program and the eligibility of children with disabilities under the SSI program was significantly narrowed. The cumulative impact of these policy and program changes may result in even more children entering foster care unless careful attention is paid to meeting the range of needs of vulnerable children and families.

Chapter 32 - Child Care

Paul H. Dworkin

Profound social and demographic changes have resulted in an increasing number of children receiving a portion of their care from someone other than their parents. In the United States, almost two thirds of mothers with children younger than 6 yr are working outside the home, including more than one half of mothers of infants and toddlers. A high divorce rate and increase in births to single women have contributed to approximately one child in four living within a single-parent household headed by the mother. Women work for the same reasons as men—economic necessity and personal choice. The economic climate and changes in family structure have necessitated the availability of child-care services for working parents.

Child care is defined as care provided by an individual outside the nuclear family or in a setting separate from the child's home and is inclusive of such services as baby sitting, daycare, preschool, early childhood program, Head Start, and nursery school. By the mid-1990s, approximately 6 million infants and toddlers in the United States were in some type of child care. Options for families generally include in-home care, family child care, and center child care. Child care is used for children of all ages. Less than 5% of children of working parents receive in-home care, in which a relative or a nonrelative (such as a nanny, housekeeper, or regular sitter) comes to the child's home to provide care. Approximately 20% of all preschool children who receive supplemental care are in regulated or nonregulated family child care, in which a small group of children, typically six or fewer, receive care in the private home of a caregiver. Nearly one half of employed mothers of 3- and 4-yr-old children report center care as their primary supplemental arrangement. Child-care centers provide care for more than six to 10 children at a time and include for-profit centers, which may be independent or operated by large chains, and nonprofit centers, which may be independent or sponsored by the government (e.g., Head Start), religious organizations, public schools, community agencies, or employers. Most child-care centers are licensed, although standards vary from state to state. Different types of child care have advantages and disadvantages, including cost, familiarity of care provider and environment, convenience, availability, flexibility in scheduling, and reliability. From a developmental perspective, the progression from care in the child's own home to care in another home with a few other children to large-group care may be appropriate. Yet for most families, decisions about child care are based largely on considerations of cost, distance from home, and safety.

The effect of child care on children's development depends on a number of interrelated factors, including the quality and quantity of the child-care experience, as well as characteristics of the child and family. Despite the substantial time spent by children in child-care settings, the predominant influences on children's adjustment and development are the parents and the home environment. The developmental effects of child care are determined by the quality of the interactions and experiences they provide. Child care can protect children from the detrimental effects of maternal depression and poverty. Care provided by insensitive or unresponsive providers can exacerbate difficult family circumstances.

High-quality child care can favorably influence the cognitive and social development of children, especially those from disadvantaged populations. Such children perform better on school entry on standardized tests of intelligence, academic achievement, and measures of accomplishment such as grades and teacher ratings. Conversely, poor-quality child care can adversely affect developmental outcomes. Contrary to popular beliefs, middle-class children are not protected from the effects of poor-quality child care. More time spent in nonmaternal care during the preschool years may be associated with more aggressive, assertive, and defiant behaviors.

Good-quality child care has been associated with a low adult-to-child ratio, small group size, and caregiver training in child development. Other important determinants include a caring and supportive staff that is stable and consistent, a developmentally appropriate curriculum that enables children to learn through a variety of fun activities, and a physical setting that affords cleanliness, sanitation, and adequate space for activities and rest as well as protection from environmental hazards. Unfortunately, child care in the United States is often of poor quality. A study of child-care centers in four states found that only 14% of centers gave good-quality care, with the remaining centers rated as mediocre or poor, often endangering the health and safety of young children. A study of family daycare yielded similar findings, with only 12% of regulated family child-care homes found to provide high-quality care. Only 3% of unregulated family child care was considered high quality, as was only 1% of the care provided by relatives in their own homes.

The lack of national standards for child care and uneven regulation from state to state contribute to the variable quality of child care in the United States. *Licensure* signifies that minimal health, safety, and sanitary practices are being followed, whereas *accreditation* (by the National Association for the Education of Young Children [NAEYC]) suggests a program is of

sufficient quality to promote children's development. The American Academy of Pediatrics and the American Public Health Association have published standards for health and safety in child-care programs. The NAEYC also has developed criteria for good child-care practice. Yet a national survey of state regulations for center-based infant and toddler care found that no state regulations fulfill the criteria for good practice, and the majority reflect poor or very poor practice. Efforts to upgrade the quality of child care are likely to require the establishment of federal standards that address such characteristics as staff-to-child ratios, group size, caregiver training, and improved salaries for child-care providers. Additional critical policy issues include parental leave, tax credits for child care, flexible work schedules, and on-site

child care provided by employers.

Pediatric providers may assume a number of important roles in promoting successful child-care experiences. Pediatricians can help parents become informed consumers by discussing the advantages and disadvantages of various child-care options, providing accurate information regarding implications for children's health and development, and directing parents to sources of information about child care in the community. The pediatrician can provide guidance to parents regarding a sick child's participation in child care and serve as health consultant to child-care programs. Pediatric advocacy for the availability of high-quality care for all children includes encouraging the implementation of national child-care standards, paid parental infant care leaves, and improved salaries and training for child-care providers.

Chapter 33 - Separation, Loss, and Bereavement

All children experience involuntary separation from loved ones, think about death, and encounter death in everyday events. Parents and children often turn to their pediatrician and other health care professionals to help them with all types of loss. Relatively brief separations of children from their parents, such as vacations, usually produce minor transient effects, but more enduring and frequent separation may cause significant sequelae. The potential impact of each event must be considered in light of the age and stage of development of the child and the particular relationship with the absent person as well as the nature of the situation. As a trustworthy, familiar resource, pediatricians are uniquely positioned to offer information, support, and guidance and to facilitate coping.

33.1 Separation & Loss

Richard Dalton

The initial reaction of *young children* to separation may involve crying, either of a tantrum-like, protesting type or of a quieter, sadder type. After a few hours or a day or so of separation, children may appear more subdued, withdrawn, and quiet or irritable, fussy, moody, and resistant to authority. Disturbance of appetite may occur, and there may be special difficulties at bedtime, such as reluctance to go to bed and problems in getting to sleep, with a resurgence of old fears and, in younger children, perhaps such regressive behavior as bed-wetting. Children may repeatedly ask where the absent parent is and when he or she will return home. Some children may not refer to parental absence at all. The child may go to the window or door or out into the neighborhood looking for the absent parent; a few may even leave home or their places of temporary placement to search for their parents. This last rather unusual response needs to be considered when a child cannot be found for a while shortly after the separation or departure of a parent.

A child's *response to reunion* may surprise or alarm a parent who is not prepared. A parent who joyfully returns to the family may be met by wary or cautious children, who, after a brief interchange of affection, may move away from the parent and seem indifferent to his or her return. The interpretation of this response depends on the child and his or her style; it may indicate anger at being left and wariness that the event will happen again, or, because children tend to personalize, the child may have felt that he or she caused the parent's departure. For instance, if the mother who frequently says “Stop it, or you'll give me a headache” is hospitalized, the child may unrealistically feel at fault and guilty. As a result of these feelings, children may seem to be more closely attached to the other parent than to the absent one, or even to the grandparent or baby sitter who cared for them during their parent's absence.

Immediately after the reunion or after a few days, some children, particularly younger ones, may become more clinging and dependent than they were before separation, while continuing any regressive behavior that had occurred during separation. Such behavior may engage the returned parent more closely and help to re-establish the bond that the child felt was broken. Such reactions are usually transient; within 1–2 wk, children will have recovered their usual behavior and equilibrium. Recurrent separations may tend to make children more wary and guarded about re-establishing the relationship with the repeatedly absent parent, and these traits may affect other personal relationships. Parents should not try to ameliorate a child's behavior by threatening to leave.

Experiences of loss such as *divorce* or *placement in foster care* can give rise to the same kinds of reactions listed earlier, but they are more intense and possibly more lasting. School-aged children may respond with evident depression, seem indifferent, or be markedly angry. Other children appear to deny or avoid the issue, behaviorally or verbally. Most children may cling to the hope or fantasy that the actual placement or separation is not real. Guilt may be generated by the child's feeling that this loss, separation, or placement represents rejection and perhaps punishment for misbehavior. Children may protect a parent at their own expense, believing and asserting that their own badness caused the parent to depart or to place them with relatives or strangers, rather than that the parent has been bad or irresponsible. Besides having their own feelings of guilt, children cannot blame their parents because they sense it may be fairly risky. Parents who discover that a child harbors resentment might punish further for these thoughts or feelings. Children who feel that their misbehavior caused their parents to separate or become divorced have the fantasy that their own trivial or recurrent behavioral patterns have caused their parents to

become angry with each other. Some children develop behavioral or psychosomatic symptoms and unwittingly adopt a “sick” role as a strategy for reuniting their parents.

In response to separation and divorce of parents, *older children and adolescents* commonly show more intense anger. Almost all children cling to the magical belief that their parents will reunite after divorce. Wallerstein found that 5 yr after the breakup, about one third of the children studied were “consciously and intensely unhappy and dissatisfied with their life in the post-divorce family.” Another one third showed clear evidence of a satisfactory adjustment, and the remaining one third demonstrated a mixed picture with good achievement in some areas and faltering achievement in others. After 10 yr, 45% were doing well, but 41% were poorly adjusted and had academic, social, and emotional problems. As they entered adulthood, many were reluctant to form intimate relationships, fearful of repeating their parents' experience. A large-scale British study indicates that parental divorce had a moderate long-term negative impact on the adult mental health status of children who had experienced it, even after controlling for changes in economic status and problems before divorce. Good adjustment of children after a divorce is related to ongoing involvement with two psychologically healthy parents who minimize conflict and to the support system offered by siblings and other relatives. Divorcing parents should be encouraged to avoid the adversarial process and to use a trained mediator if they cannot resolve disputes on their own. Joint custody arrangements may reduce ongoing parental conflict, but children in joint custody felt overburdened by the demands of maintaining a strong presence in two homes.

Another version of a separation experience occurs when a child's family *moves*. A significant proportion of the population of the United States changes residence each year. The effects of this movement on children and families are frequently overlooked; for children, the move is essentially involuntary. When such changes in family structure as divorce or death precipitate moves, children face the stresses created by both the precipitating events and moving itself. When parents are sad because of the circumstances surrounding the move, this unhappiness will be transmitted to their children. Children who move lose their old friends, the comfort of a familiar bedroom and house, and their ties to school and community. They not only must sever old relationships but also are faced with developing new ones in new neighborhoods and new schools. Children may enter neighborhoods with new and different customs and values, and because academic standards and curricula vary among communities, children who have performed well in one school may find themselves struggling in a new one. Frequent moves during the school years are likely to have adverse consequences on social and academic performance.

Migrant children and families present as a special population (see Chapter 39). Migrant children not only need to adjust to a new community, school, and house but also need to adjust to a new culture and, in many cases, to a new language. Because children have faster language acquisition, they may function as translators for the adults in their families. This powerful position may lead to role reversal and potential conflict within the family. Migrant children are more likely to come from families with low socioeconomic status, live in overcrowded conditions, and have poorly educated parents. All of this, plus the previously mentioned factors, can increase the risk for psychopathologic disorders. In the evaluation of migrant children and families, it is also important to ask about the circumstances of the migration; legal status; conflict of loyalties; and moral, ethical, and religious differences.

Parents should prepare children well in advance of any move and allow them to express any unhappy feelings or misgivings. Parents should acknowledge their own mixed feelings and agree that they will miss their old home while looking forward to a new one. Visits to the new home in advance are often useful preludes to the actual move. Transient periods of regressive behavior may be noted in preschool children after moving, and these should be understood and accepted. Parents should assist the entry of their children into the new community, and exchanges of letters with old friends and visits, whenever possible, should be encouraged.

33.2 Grief and Bereavement

Linda Sayler Gudas
Gerald P. Koocher

Grief is a personal, emotional state of bereavement or an anticipated response to loss. Not all children and families require intensive professional intervention during or following a loss event; and the presence of symptoms such as sadness, yearning, searching, and loneliness are understandable and predictable. Most bereaved families remain socially connected and expect that life will return to some new, albeit different, sense of normalcy. However, the pain and suffering imposed by grief should never be automatically deemed “normal” and thus neglected or ignored. In uncomplicated grief reactions, the steadfast concern of the pediatrician can help promote the family's sense of well-being. In more distressing reactions (such as those seen in traumatic grief), the pediatrician may be a major, first-line force in helping children and families address their loss.

Participation in the care of *a child with a life-threatening or terminal illness* is a profound experience. See Chapter 38 for discussion of palliative and end-of-life care. Withholding of information from children and parents by providers regarding diagnosis and prognosis has generally been abandoned as physicians have learned that protecting patients from the seriousness of their condition does not alleviate concerns and anxieties. Even very young children may have a real understanding of their illness. Children should be told early in their treatment that they have a very serious illness, that people can die of it, but promising treatments and medicines will help.

A death, especially the *death of a family member*, is the most difficult loss for a child. Many secondary losses occur as a result of a family death (e.g., change in income, possible need to relocate, less emotional support from surviving family members, altering of routines, change in status from sibling to only child). The presence of secure and stable adults who can meet the child's needs and who permit discussion about the loss is most important in helping a child grieve. The pediatrician should help the family understand this necessary presence and encourage the protective functioning of the family unit.

Death, separation, and loss as a result of natural and man-made *catastrophes* have become increasingly common events in children's lives. Exposure to such disasters occurs either directly or indirectly, where the event is experienced through the media.

The televised scenes of the terrorist attacks in the United States on 9/11/01, subsequent news stories about anthrax, and heightened states of alert exemplify such indirect exposure. Studies have demonstrated that children who experience personal loss in disasters tend to watch more TV coverage than children who do not. However, children without a personal loss watch as a way of participating in the event and may thus experience repetitive exposure to traumatic scenes and stories. The loss and devastation for a child who personally lives through a disaster is significant; the effect of the simultaneous occurrence of disaster and personal loss complicates the bereavement process, as grief reactions become interwoven with post-traumatic stress symptoms (Chapter 22). After a death that occurs as a result of aggressive or traumatic circumstances, access to expert help may be required. Under conditions of threat and fear, children seek proximity to safe, stable, protective figures.

Developmental Perspective.

Children's responses to death reflect the family's current culture, past heritage, and sociopolitical environment. Personal experience with terminal illness and dying may also facilitate children's comprehension of death and familiarity with mourning. However, developmental differences in children's efforts to make sense of and master the concept and reality of death do exist and profoundly influence their grief reactions.

Infants and toddlers do not understand all dimensions of death, especially its permanence. However, primitive protest, despair, separation anxiety, and detachment may occur at withdrawal of nurturing caretakers. Very young children also respond in reaction to observing distress in others. Young children also express signs and symptoms of grief in their emotional states, such as irritability or lethargy. In severe cases of grief, failure to thrive may occur. Also see Chapter 36 .

The thinking processes of preschool years is prelogical, egocentric, and circular. Preschool children do not show well-established cause and effect reasoning. They typically express magical explanations of death events, sometimes resulting in guilt and self-blame (e.g., “He died because I wouldn't play with him.”). Children conceptualize events in the context of their own experiential reality, and therefore consider death in terms of sleep, separation, and injury. In attempts to master the finality and permanence of death, preschoolers frequently ask unrelenting, repeated questions such as “After he finishes getting dead, will Johnny go on vacation with us?” or “When will they put the plane that crashed back together, so Mommy can fly home to make dinner?” Young children will express grief intermittently and show marked affective shifts over brief periods of time. Regression, accompanied by longing, sadness, and anger may accompany grief.

School-aged children think more concretely, recognize the permanence of death, and begin to understand biological processes of the human body (e.g., “You'll die if your body stops working.”). Information gathered from the media, peers, and parents form lasting impressions. Consequently, they may ask candid questions about death that adults will have difficulty addressing (e.g., “He must have been blown to pieces, huh?”). Those in middle childhood, the elementary school years, tend to experience more anxiety, more overt symptoms of depression, and more somatic complaints than do younger children. School-aged children are often left with anger focused on the loved one, those who could not save the deceased, or those presumed responsible for the death. Contact with the pediatrician may provide great reassurance, especially for the child with somatic symptoms, and particularly when the death followed medical illness. School and learning problems may also occur, reactions often linked to concentration difficulties or preoccupation with the death. Close collaboration with the child's school may provide important diagnostic information and offer opportunities to mobilize intervention or support.

Around the age of 12 yr, children begin to use symbolic thinking, reason abstractly, and analyze hypothetical or “what if” scenarios systematically. Death and end of life become concepts, rather than events. *Teenagers* begin to understand complex physiologic systems in relationship to death. A developing sense of autonomy and personal identity, coupled with intense physiologic changes, makes adolescents prone to increased interest in bodily functions and focus on themselves. Fascination with dramatic, sensational, or romantic death sometimes occurs and may find expression in copycat behavior (e.g., cluster suicides) as well as competitive behavior to forge emotional links to the deceased person (“He was my best friend.”). Somatic expression of grief may revolve around highly complex syndromes (e.g., eating disorders or conversion reactions) as well as symptoms limited to the more immediate perceptions as with younger children (e.g., stomachaches). Quality of life takes on meaning, and the teenager develops a focus on the future. Depression, resentment, mood swings, rage, and risk-taking behaviors can emerge as the adolescent seeks answers to questions of values, safety, evil, and fairness. Alternately, the adolescent may seek philosophical or spiritual explanations (e.g., “being at peace”) to ease their sense of loss. Death of a peer may be especially traumatic.

Role of the Pediatrician in Grief.

Children often demonstrate that open discussion of their grief provides relief, and they readily share their story with others. Terr and colleagues found that school-aged children often attempt to cope with traumatic loss by seeking out and acquiring information on their own. As a source of accurate and reliable information, the pediatrician should reserve time to meet with the child, parents, and/or entire family to discuss concerns and assess the level of functioning. The pediatrician can perform several preventive roles in such meetings.

The first role is to be an educator about disease, death, and grief. The pediatrician should prepare to address questions such as “Can this happen to me (or someone else I care about)?” “What will happen next?” “Did she suffer?” One need not elaborate on all such questions at one time, but truthful accounts presented in understandable language will help considerably. Even for very young children, clear and honest explanation of what has happened enhances coping. For example, “Dad's heart stopped beating forever because it was damaged in the automobile accident. He doesn't breathe or eat or move anymore. When those things happen, you are dead. Dad can never be alive again.” In attempting to make sense of their loss, children and parents often become angry with health care professionals for “letting” their loved one die. School-aged children often concretely believe in the omnipotence of physicians and may also have been told “Dr. Jones will make Mommy better.” Questions such as “Why didn't you…” should be answered in a responsive manner and without defensiveness. For example, “We did everything we could for your Mom. I'll be happy to answer any specific questions you have about her care. Sometimes it's hard to understand why someone we love has to die and

leave us.”

The pediatrician also can offer a safe environment to talk about painful emotions, express fears, and share memories. By giving families permission to talk and by modeling how to address children's concerns, the pediatrician demystifies death. Parents often request practical help. By providing resources, such as literature (both fiction and nonfiction) or referrals to therapeutic services, and offering families tools to learn about illness, loss, and grief, the physician reinforces the sense that other people understand what they are going through and helps normalize their distressing emotions. The pediatrician can also facilitate and demystify the grief process by sharing basic tenets

of grief therapy. There is no single right or wrong way to grieve. Everyone grieves differently, and children mourn differently from adults. Grief is not something to “get over” but is a life-long process of adapting, readjusting, and reconnecting.

In addition, the pediatrician should assess routine health and life skills in families affected by loss and coach the family toward a sense of cohesion, moving gradually toward normalcy. Parents and children often report feeling so overwhelmed by grief that they cannot organize and manage such daily tasks as meal preparation or homework. Children cope best with grief in homes where caretakers provide safe, consistent, and predictable routines and life patterns.

The pediatrician's knowledge and understanding of child development can assist in planning age-appropriate solutions and, in a non-authoritarian manner, help families reach decisions about such questions as “How do we tell the children?” “Does he know he's dying?” “Will I get cancer?” “Do I have to tell the kids at school?” “Should Sarah watch TV coverage of the scary event?” “When will things be normal?” “Should Johnny go to the funeral?” For example, the pediatrician might first help parents identify important data to assist in the decision (e.g., “What would Johnny prefer?” “What do you believe you should do?” “What will help him feel most safe and emotionally connected to others at this sad time?”). Second, a review of what might happen and what to tell Johnny might occur (e.g., “There will be a lot of people at the funeral. Some will be crying because they are sad and miss the dead person. A box called a casket will have the body in it.”). Finally, adaptive alternatives could be presented to the family (e.g., “Could Johnny have a private showing with just the family present?” “Would Johnny prefer finding ways to remember his brother without attending the service?”).

Clinicians must remain vigilant for risk factors in each family member and in the family unit as a whole. Primary care providers, who care for families over time, know bereft patients' premorbid functioning and can identify those at current or future risk for physical and psychiatric morbidity. Providers must focus on symptoms that interfere with a patient's normal activities and compromise a child's attainment of developmental tasks. Symptom duration, intensity, and severity, in context with the family's culture, can help identify complicated grief reactions in need of therapeutic attention. Descriptive words such as *unrelenting*, *intense*, *intrusive*, or *prolonged* should raise concern. Total absence of mourning signs, specifically an inability to discuss the loss or express sadness, should also suggest potential problems.

No specific grief sign, symptom, or cluster of behaviors identifies the child or family in need of help. However, further assessment is indicated if the following occur: (1) persistent somatic or psychosomatic complaints of undetermined origin (e.g., headache, stomachache, eating and sleeping disorders, conversion symptoms, symptoms related to the deceased's condition, hypochondriasis); (2) unusual circumstances of death or loss (e.g., sudden, violent, or traumatic death; inexplicable, unbelievable, or particularly senseless death; prolonged, complicated illness; unexpected separation); (3) school/academic/work difficulties (e.g., declining grades or school performance, social withdrawal, aggression); (4) changes in home/family functioning (e.g., multiple family stresses, lack of social support, unavailable or ineffective functioning of caretakers, multiple disruptions in routines, lack of safety); (5) concerning psychologic factors (e.g., persistent guilt or blame, desire to die or talk of suicide, severe separation distress, disturbing hallucinations, self-abuse, risk-taking, symptoms of trauma such as hyperarousal or severe flashbacks, grief from previous or multiple deaths).

Treatment.

Suggesting interventions outside the natural support network of family and friends can often prove useful to grieving families. Interventions that enhance or promote attachments and security, as well as give means of expressing and understanding death, help to reduce the likelihood of future or prolonged disturbance, especially in children. Collaboration between pediatric and mental health professionals can help determine timing and appropriateness of services.

Often overlooked interventions for children and families struggling to cope with a loss in the community include positive activities enabling conversation about or active coping with their grief. For example, sending a card or offering food to relatives of the deceased can help children learn the etiquette of behaviors and rituals around bereavement and mutual support. Performing community service or joining charitable organizations, such as fund-raising in memory of the deceased, often prove useful. In the wake of a disaster, parents and older siblings can give blood or volunteer in search and recovery efforts. When a loss does not involve an actual death (e.g., such as parental divorce or geographic relocation), empowering the child to join or start a “divorced kids' club” in school or planning a “new kids in town” party may help. See Chapter 33.1 . Participating in constructive activity helps move the family away from a sense of helplessness and hopelessness and facilitates meaning in their loss.

Psychotherapeutic services may benefit the entire family or individual members. Many support or self-help groups focus on specific types of losses (e.g., sudden infant death syndrome, suicide, widow/widowers, or AIDS) and provide an opportunity to talk with other people who have experienced similar losses. Family, couple, or individual counseling may be useful depending on the nature of the residual coping issues. Combinations of approaches may work well for children or parents with evolving needs. For example, a child may participate in family therapy to deal with the loss of a sibling and use individual treatment to address issues of personal ambivalence and guilt feelings related to the death.

The question of pharmacologic intervention for grief reactions often arises in the

pediatrician's office. Explaining that medication does not cure grief and often does not reduce the intensity of some symptoms (e.g., separation distress) can help. Although medication can blunt reactions, the psychologic work of grieving still must occur. The pediatrician must consider the patient's premorbid psychiatric vulnerability, current level of functioning, other available supports, and the use of additional therapeutic interventions. Medication, as a first line of defense, rarely proves useful in normal or uncomplicated grief reactions. In certain situations (e.g., severe sleep disruption, incapacitating anxiety, or intense hyperarousal), use of an anxiolytic or antidepressant medication for symptom relief and to provide the patient with the emotional energy to mourn may help. Medication used in conjunction with some form of psychotherapy, and in consultation with a psychopharmacologist, has optimal results. See Chapter 28 .

Future Considerations.

In recent years, the field of bereavement intervention has faced new challenges, for which scant research and experience exist as guides. One such area involves helping children and families cope in the aftermath of horrific, inexplicable deaths and losses such as terrorist attacks on civilians. The effects of chronic exposure to massive death and destruction, the lack of what Brooks and Siegel refer to as a "geographic safety zone" in which to feel secure, and the identification and management of long-term traumatic grief reactions to such attacks have not been investigated in the pediatric population. Another understudied direction involves addressing help for children and families to cope with grief in nontraditional ways. Health care providers must develop increased sensitivity and cultural awareness to attitudes about death and the rituals surrounding mourning in families of different ethnic and religious beliefs and in multicultural families practicing more pluralistic beliefs (see Chapter 3).

Chapter 34 - Impact of Violence on Children

Marilyn Augustyn
Barry Zuckerman

Violence in the United States is a public health epidemic, affecting victim, witness, and perpetrator. The focus of pediatrics should not be limited to the traditional care of violence-related injury. Exposure to violence disrupts the healthy development of a great many children, and pediatricians need to be aware of this threat. Pediatric providers also have a wider responsibility to advocate on local, state, and national levels for safer environments in which all children can grow and thrive.

The source of first exposure to violence for children is often *domestic violence*. Occasional wife battering is estimated to exist in 16% of all families, and 3.4% (or 1.8 million women) are beaten regularly by their husbands. One study found that 40% of mothers reported violence in their families as a way of “settling disagreements.” Family violence is most likely to be perpetrated by those between ages 18 and 30 yr—“the child-rearing years.” It is not surprising, then, that the majority of children in these homes have witnessed violence; one study estimated that 3 million children witness domestic violence every year. In a series of 62 domestic incidents, children were *victims* in 15% of domestic violence incidents. Most of the children were injured when they intervened to protect their mother from her partner (see Chapter 35). *Witnessing* violence is only currently being recognized as detrimental to children. Because their scars as bystanders are emotional and not physical, the pediatric clinician may not fully appreciate their distress and thereby miss an opportunity to provide needed interventions.

Another source of witnessed violence is *community violence*. More than one third of New Orleans school-aged children had witnessed severe violence, and 40% had seen a dead body. In inner-city Boston, a study of mothers in a pediatric clinic found that 10% of children younger than 6 yr had seen a knifing or shooting. In Los Angeles County, the Sheriff's Office estimates that children witness 20% of all murders. Young children living in high crime and violence areas observe death more frequently and at younger ages than children growing up in more secure surroundings.

The most ubiquitous source of exposure to violence for children in the United States is *television*. The average child 2–5 yr of age watches 20 to 30?hr of television a week, hours that are increasingly filled with scenes of violence. More than 3,500 research studies have examined the association between media violence and violent behavior; all but 18 have shown a positive relationship. Perhaps the most significant event that brought home the power and significance of media exposure on children is September 11, 2001. Children watched TV coverage of the attacks for a mean of 3.0?hr on September 11; only 34% of parents reported that they restricted their children's television viewing. Although exposure to media violence cannot be equated to exposure to “real-life” violence, many studies confirm that media violence desensitizes children to the meaning and impact of violent behavior. In the case of September 11th, among children whose parents did not try to restrict television viewing, there was an association between the number of hours of television viewing and the number of reported stress symptoms. Not all children are affected by television violence. Children most at risk from viewing television violence may be children who are also exposed regularly to real-life violence in their homes and communities.

Real-life violence continues to be a major problem in the United States. About 20,000 people in the country die each year as a result of intentional homicide. The leading cause of death in both black and white teenage males in the United States is gunshot wounds. The Massachusetts Department of Education found in a 1995 survey that one in five public high school students carried a weapon on or off school property in the 30 days before the survey. One in 20 had carried a gun. Even more common is bullying, with almost 30% of a large sample of sixth and 10th graders reporting that they have participated in bullying, being bullied, or both.

The violence children experience and witness also has a profound impact on health and development. Beyond injuries, violence affects children psychologically and behaviorally; it may influence how they view the world and their place in it. Children can come to see the world as a dangerous and unpredictable place. This fear may thwart their exploration of the environment, which is essential to learning in childhood. Furthermore, high exposure to violence in children correlates with poorer performances in school, symptoms of anxiety and depression, and lower self-esteem. Violence, particularly domestic violence, also can teach children especially powerful early lessons about the role of violence in relationships. Perhaps the most sobering consequence is that violence may change the way that children view their future—they may believe that they may die at an early age and thus take more risks, such as drinking alcohol, abusing drugs, not wearing seatbelts, and not taking prescribed medication.

Research suggests that high levels of witnessing violence places children at risk for psychologic, social, academic, and physical problems, as well as for engaging in violent acts themselves. (See also Chapter 39 .) Mental health effects may include depression, dissociation, aggression, and substance abuse. Some children exposed to severe and/or chronic violence may suffer from post-traumatic stress disorder (PTSD), exhibiting constricted emotions, difficulty concentrating, autonomic disturbances, and re-enactment of the trauma through play or action (see Chapter 22). A particular challenge in treating and diagnosing pediatric PTSD is that a child's caregiver exposed to the same trauma may be suffering from it as well.

The simplest way to recognize whether violence has become a problem in a family is to consistently question both patients

(when they are old enough) and parents. This is particularly important during pregnancy and the immediate postpartum period when women may be at highest risk for abuse. It is important to assure families that they are not being singled out but that all families are asked about their exposure to violence. For some families a direct approach is useful: for example, “Violence is a major problem in our world today and one that impacts everyone in our society. Thus I have started asking all my patients and families about violence that they are experiencing in their lives….” In other cases, beginning with general questions and then moving to the specific may be helpful. For example, “Do you feel safe in your home and neighborhood? Has anyone ever hurt you or your child?” When violence has impacted the child, it is important to gather details about symptoms and behaviors.

Many parents and children who have been exposed to violence can be effectively counseled by the pediatrician. Matters to be covered include gathering the facts and details of the event, gaining access to support services, providing information about the symptoms and behaviors common in children exposed to violence, and helping parents talk to their children about the event. When the symptoms are chronic (more than 6 mo) or not improving, if the violent event involved the death or departure of a parent, if the caregivers are unable to empathize with the child, or if the ongoing safety of the child is a concern, it is important that the family be referred to mental health professionals for additional treatment.

Chapter 35 - Abuse and Neglect of Children*

Charles F. Johnson

Child maltreatment encompasses a spectrum of abusive actions, or acts of commission, and lack of action, or acts of omission, that result in morbidity or death (Fig. 35–1). Acts of omission and commission before birth, such as maternal drug abuse and failure to seek appropriate health care during pregnancy, may also have adverse effects on the child. Physical abuse may be narrowly defined as intentional injuries to a child by a caregiver that result in bruises, burns, fractures, lacerations, punctures, or organ damage. A broader definition would include short- and

Figure 35-1 The spectrum of child maltreatment. Child maltreatment encompasses acts of commission, or abuse, and acts of omission, or neglect, by a caretaker that adversely affect children. The act can be physical or psychologic. The boundaries between these areas are indistinct and psychologic; physical abuse and neglect overlap and may exist at the same time or various times in the child's life. Sexual abuse may be considered a specific type of physical abuse that has strong emotional components. Physical abuse and neglect invariably have short- and long-term psychologic consequences. Psychologic consequences may persist long after the physical wounds heal.

long-term emotional consequences, which can be more debilitating than the physical effects. Physical neglect and other acts of omission may result in failure to thrive, develop, and learn and increased susceptibility to infection. Nutritional neglect is the most common cause of underweight in infancy and may account for more than half the cases of failure to thrive (see Chapter 36). Physicians are most likely to identify medical neglect that results from the failure of a parent to provide appropriate medical care, whereas failure to provide shelter, schooling, adequate clothing, and protection from environmental hazards tends to be observed by neighbors, relatives, teachers, and social workers. Medical neglect of a child with an acute or chronic disease may result in worsening of the condition and death.

Parents may refuse to allow recommended medical treatments because of personal or religious beliefs. The determination of whether this constitutes neglect and, if so, the appropriate action for a physician to take is a difficult decision (see Chapter 2). Neglect of appropriate precautions by caregivers to ensure a child's safety may also involve difficult matters of judgment. Children may be injured despite a variety of protective actions by well-meaning parents.

Psychologic maltreatment includes intentional verbal or behavioral acts or omissions that result in adverse emotional consequences. A caregiver may intentionally fail to provide nurturing verbal and behavioral actions that are necessary for healthy development. Psychologic maltreatment of a child by a caregiver includes spurning, exploiting/corrupting, withholding emotional responsiveness, isolating, or terrorizing. Psychologic maltreatment may be difficult to document when psychopathology

* Some parts of this chapter were adapted from previous sections by B. D. Schmitt and R. D. Krugman.

or emotional consequences must be shown to be the direct result of acts or omissions by caregivers. *Sexual abuse* refers to any act intended for the sexual gratification of an adult. Sexual abuse may be perpetrated by family members (incest), acquaintances, or, least often, strangers.

Medications and toxins may be given to intentionally poison a child. When this or any other deceptive action is undertaken to simulate a disorder, it is referred to as *Munchausen syndrome by proxy.* The induced symptoms and signs may lead to unnecessary medical investigation, hospital admissions, or treatment; death occurs in as many as 10% of these cases.

Legal definitions of what constitutes abuse and neglect vary from state to state. Physicians and other providers of care to children are required by law in all 50 states to report suspected child abuse or neglect. These laws afford protection from lawsuits to mandated reporters who report in good faith; they also allow for clinical and laboratory evaluations and documentation without the parent's or guardian's permission. Failure to report suspected child abuse may result in a penalty. It may also result in a malpractice claim for damages incurred as a result of failure to report and thereby protect the child from further injury.

Epidemiology.

Since 1993, victimization rates per 1,000 children have declined to 11.8. After mandated reporting began in the 1960s, the number of reports to Children's Protective Services (CPS) and law enforcement agencies in the county in which the alleged abuse or neglect occurred had steadily increased. In 1976, there were 669,000 reports of child maltreatment. This number reached 3.0 million in 1995 (1 in every 25 children). The initial increase in reports has been attributed to improved case finding and reporting. In 1995, 36% (1.0 million) reports were “substantiated” by CPS. In 1999, of an estimated 2,974,000 referrals, 39.6% were screened out by CPS agencies. There were an estimated 826,000 victims. An estimated 1,100 children died of abuse in 1999. Children younger than 1 yr accounted for 42.6% of the fatalities. Neglect was the most common cause of death (38.2%). With the advent of child death review teams, it is expected that more child abuse deaths will be revealed. The prevalence of abuse is unknown. A survey of families with children aged 3–18 yr indicated that 140 of 1,000 (14%) were kicked, bitten, punched, hit with an object, beaten up, or threatened with a knife or gun in 1 yr. A 1995 Gallup telephone survey indicated that 49 of every 1,000 children (5%) may have been physically abused. Approximately 10% of injuries to children younger than 5 yr who are seen in emergency departments are due to abuse; 15% of children admitted for

burns and 50% of children younger than 1 yr of age with fractures have been abused. In 1999, The National Child Abuse and Neglect Data System (NCANDS) indicated that neglect, physical abuse, and sexual abuse constituted 58.4%, 21.3%, and 11.3%, respectively, of confirmed cases. The rate of maltreatment declined with advancing age. Of perpetrators, 62% were female. Males were the most common perpetrators of sexual abuse.

Although varying definitions and reporting requirements prevent detailed comparisons, parents who abuse their children have been reported from most ethnic, geographic, religious, educational, occupational, and socioeconomic groups. In the 1999 NCANDS report, ethnicity of victims ranged from a low of 4.4/1,000 children for Asian/Pacific Islander victims to 25.2/1,000 of African-American victims. Groups living in poverty have increased reports of physical abuse because of (1) the increased number of crises in their lives (e.g., unemployment or overcrowding), (2) limited access to economic or social resources for support during times of stress, (3) the increased violence in the communities where they live, (4) an association of poverty with other risk factors, such as teenage and single parenthood and substance abuse, and (5) the possibility of more scrutiny by community agencies and neighbors. An increased incidence of physical abuse has been noted on military bases. This may be due to increased surveillance as well as increased risk factors. The presence of spouse abuse increases the likelihood of child abuse (see Chapters 5 and 34). Substance abuse is a common finding in families with abused children. More than 90% of abusing parents have neither psychotic nor criminal personalities. Rather, they tend to be lonely, unhappy, angry, young, single parents who do not plan their closely spaced pregnancies, have little or no knowledge of child development and child health, and have unrealistic expectations for child behavior. Mentally retarded children are more at risk for abuse and neglect. Their parents may injure them in anger after being provoked by what they consider a misbehavior that is actually related to a handicap. From 10–40% of abusive parents have experienced physical abuse as children.

Physical abuse is most likely to occur when a high-risk parent responsible for the care of a high-risk child undergoes stress and reacts to stress with violence. High-risk children include premature infants, infants with chronic medical conditions, colicky babies, and children with learning and behavior problems. The child may be normal but misperceived by an inexperienced parent as difficult, unusual, or abnormal. Normal behavior, such as crying, wetting, soiling, and spilling, may cause the parent to lose control and injure a child. The occasion precipitating the abuse may be associated with a family crisis, such as loss of a job or home, marital strife, death of a sibling, physical exhaustion, or development of an acute or chronic physical or mental illness in the parent or child. Determination of risk factors for abuse and neglect should begin during pregnancy and continue through childhood as part of the routine medical history and in all cases of childhood injury. The presence of risk factors in parents or child should increase the suspicion of abuse; however, when abuse cannot be documented, significant risk factors may necessitate referral for preventive services.

Clinical Manifestations.

Physical abuse is suspected when an injury is unexplained, unexplainable, or implausible. If an injury is incompatible with the history given or with the child's development, suspected abuse should be reported. Diagnostic certainty of physical abuse is not required to file a report. It is expected, when children are hurt, that parents will bring them immediately for examination. A delay in seeking medical help should increase suspicion of abuse or neglect. A delay may also be due to a lack of transportation or ignorance about the significance of disease or injury. Before reporting suspected medical neglect, the physician should determine whether the parents have an understanding of disease processes and the intellectual, emotional, economic, and physical resources needed to provide for their children. A report of suspected neglect should bring needed services.

Bruises are the most common manifestation of child abuse and may be found on any body surface. Accidental bruises, from impact trauma, are most likely to be found on thin leading surfaces overlying bone edges, such as the shins, forearms, and brows. Bruises to the buttocks, genitals, back, and back of the hands are less likely to be due to an accident. Children may be struck, thrown, burned, bitten, lacerated, or punctured. The shape of the injury may suggest the object used. Paddles, belts, hands, and other instruments leave specific marks (Fig. 35–2). The most commonly used "instrument" to inflict trauma is the hand. Bilateral, symmetric, or geometric injuries should raise suspicion of child abuse. The color of a bruise is influenced by the time and depth of injury, the body surface involved, and the skin color. A fresh bruise generally appears blue or red-purple. A bruise is older if there is yellow, green, or brown. Bruises of different colors on the same body surface generally are not compatible

Figure 35-2 A variety of instruments may be used to inflict injury on a child. Often the choice of an instrument is a matter of convenience. Marks tend to silhouette or outline the shape of the instrument. The possibility of intentional trauma should prompt a high degree of suspicion when injuries to a child are geometric, paired, mirrored, of various ages or types, or on relatively protected parts of the body. Early recognition of intentional trauma is important to provide therapy and prevent escalation to more serious injury.

with a single event. Dark skin may mask bruises. Wrenching or pulling an extremity of an infant may result in a corner chip or "bucket-handle" fracture of the metaphysis. Inflicted fractures of the shaft are more likely to be spiral from twisting rather than transverse from impact. Spiral fractures of the femur before the age of walking are usually inflicted. Cardiopulmonary resuscitation or accidental impact rarely causes rib fractures or retinal hemorrhages in children. The earliest manifestation of fracture healing, manifesting as callus formation, is 7–10 days. Skull fractures cannot be dated.

Hair that is pulled causes alopecia in which the hairs are broken at various lengths. Infants who are left to lie on their backs from neglect or to prevent sudden infant death syndrome (SIDS) may have a flattened occiput with an overlying area of missing hair. Bruises, scars, internal organ damage, and fractures in various stages of healing should suggest the battered child syndrome.

Petechiae of the face and shoulders from intense retching, coughing, crying, or straining may be mistaken for abuse, as may a variety of conditions such as mongolian spots, capillary hemangiomas, pigmented nevi, and other congenital,

allergic, self-inflicted, and infectious skin conditions. A single 1-cm, round lesion of impetigo may be difficult to differentiate from a cigarette burn that has become infected. Blood dyscrasias and coagulopathies result in readier bruising. Old and new fractures may be seen in specific chromosomal disorders or rare conditions such as Wilson disease, Schmid-like metaphyseal chondrodysplasia, and osteogenesis imperfecta. Severe monilia of the diaper area may suggest an immersion burn.

Approximately 10% of cases of physical abuse involve *burns.* The shape or pattern of a burn may be diagnostic when it reflects the pattern of an object or method of injury. Cigarette burns produce circular, punched-out lesions of uniform size (Fig. 35–3). An immersion burn occurs when a child is placed in hot water intentionally or unintentionally. Immersion in 147°F water for 1?sec can result in a second-degree burn. Extremity immersions result in glove or stocking burn patterns. When a child's body is placed in hot water, the level of burn demarcation is uniform and distinct. Flexion creases may be spared when the child protectively flexes the extremities. Depending on how the child is held when immersed, the hands and feet may be spared and splash burns are not expected. The immersion burn pattern is incompatible with falling into a tub or turning on the hot water while in the bathtub. It is necessary to ascertain the developmental skills of the child, water temperature, tub height, and knob type in the investigation of scald burns. Children younger than 24 mo of age may not be able to enter a tub or turn a rotary knob. Immersion burns are most common in infants.

The most common cause of death from physical abuse is *intentional head trauma* (IHT). Twenty-nine per cent of child abuse reports from a children's hospital recorded injuries to the head, face, or cranial contents. More than 95% of serious intracranial injuries during the 1st yr of life are the result of IHT. If an injured infant presents with coma, convulsions, apnea, and increased intracranial pressure, head injury should be considered. A CT scan may reveal intracranial bleeding. An eye exam may reveal retinal hemorrhages. More subtle symptoms of central nervous system (CNS) injury, such as vomiting, irritability, or lethargy, may be misdiagnosed as due to other causes. A missed diagnosis of IHT can lead to further injury, morbidity, and mortality. A bloody spinal tap may not be iatrogenic, particularly if xanthochromia is present. Subdural hematomas in which there are no scalp marks or skull fractures may result from a blow from a hand. The source of injury may be revealed at autopsy when a subgaleal hand print is found. Although grab marks or metaphyseal fractures and rib fractures have been described in association with *shaking* (acceleration-deceleration) and slamming the head against an object, there may be no external marks or fractures. Retinal hemorrhages are seen in 85% of infants who are shaken. They occur commonly with normal birth and rarely with coagulopathies, blood dyscrasias, meningitis, endocarditis, severe hypertension, cardiopulmonary resuscitation, or impact trauma.

Intra-abdominal injuries from impacts are the second most common cause of death in battered children. Affected children may present with recurrent vomiting, abdominal distention, absent bowel sounds, localized tenderness, or shock. Because the abdominal wall is flexible, the overlying skin may be free of bruises. If the child is struck with a fist, a row of three to four 1-cm teardrop-shaped bruises in a slight curve may be seen. The blows may result in a ruptured liver or spleen or perforation or laceration of the small intestine at sites of ligamental support,

Figure 35-3 Marks from heated objects cause burns in a pattern that duplicates that of the object. Familiarity with the common heated objects that are used to traumatize children facilitates recognition of possible intentional injuries. The location of the burn is important in determining its cause. Children tend to explore surfaces with the palmar surface of the hand and rarely touch a heated object repeatedly.

such as the duodenum and proximal jejunum. Intramural hematomas at these sites can lead to temporary obstruction. Chylous ascites and pseudocyst of the pancreas also have been reported from intentional injury.

Laboratory Findings.

Screening tests should be obtained in all cases of bruising to rule out a bleeding diathesis. These tests include a prothrombin time, partial thromboplastin time, and platelet count. Abnormal results may follow intracranial bleeding. Children with a hematologic condition, or any chronic condition, may also be abused.

When physical abuse is suspected in a child younger than 2 yr, a *roentgenologic bone survey* consisting of multiple views of the skull, thorax, long bones, hands, feet, pelvis, and spine is necessary. These films should be repeated in 7–10 days to reveal healing of fractures not seen on the initial films. Bone scans may be of value in detecting new fractures of the hands, feet, or ribs. They are not valuable in detecting skull fractures. For children 2–4 yr of age, a bone survey is indicated unless the child is adequately verbal, has very minor injuries, or was in a witnessed and supervised setting (e.g., preschool) when injured. For verbal children older than 4 or 5 yr, roentgenograms need be obtained only if there is bone tenderness or a limited range of motion on physical examination. If films of a tender site are negative, they should be repeated in 7–10 days to detect any calcification, subperiosteal bleeding, or nondisplaced epiphyseal separations that were initially undetected. Bone trauma is found in 10–20% of physically abused children. Fractures considered highly specific for child abuse include metaphyseal, rib, scapular, outer end of clavicle, vertebral, and finger in preambulating children; fractures of different ages; bilateral fractures; and complex skull fractures. Midclavicular, simple linear, and single diaphyseal fractures have a low specificity for abuse. Despite an absence of CNS abnormalities, a head CT scan, ophthalmologic exam, and, if indicated, an MRI study should be obtained when an infant has been severely injured. Fractures, burns, or bruises may be associated with an old or a new head injury. Liver and pancreatic enzyme studies or an abdominal CT scan may uncover damage to these organs. Urine and stool should be screened for blood if abdominal trauma is suspected.

Diagnosis.

Suspicion of physical abuse or neglect is usually based on a history that is not in keeping with physical findings or the child's developmental stage. All information should be legibly recorded. All visible lesions should be photographed with a quality analog or digital camera. Color charts, patient identification, and measuring scales should be included in the field. An analysis of the circumstances of the injury is

critical. For example, the consequences of a fall depend on (1) child variables, such as surface contacted, age, size, motor skills, motor tone, clothing, and momentum, and (2) environmental variables, such as distance and physical qualities (soft, hard, padded, sharp, dull) of contact surfaces. Data from studies of witnessed falls from hospital beds, bunk beds, windows, and school yard equipment have been used to estimate the force required to cause brain damage and fractures. A fall from 3?ft may rarely result in a simple linear fracture of the skull or clavicle. Falls from 6?ft may rarely result in concussions, subdural hemorrhages, or lacerations. There are no reports of death or severe brain injury from *witnessed* falls of less than 10?ft.

After separation from caretakers, a child older than age 3 yr may be able to tell a sensitive and skillful interviewer that a particular adult hurt him or her. Children may not give a history of intentional injury if they are concerned about retribution from the perpetrator or separation from their home, school, siblings, friends, or nonoffending parent.

The differential diagnosis depends on the particular injuries. For example, roentgenograms of bones in scurvy and syphilis and normally growing bone shafts of infants may resemble nonaccidental bone trauma. The bony changes in these conditions are often symmetric. Children with osteogenesis imperfecta, severe osteomalacia, or sensory deficits (e.g., myelomeningocele or paraplegia) have an increased incidence of pathologic fractures, but rarely of the metaphysis.

Treatment.

Appropriate medical, surgical, and psychiatric treatment should be promptly initiated. The law requires that a child *suspected* of being abused or neglected be reported immediately to CPS. Children with suspected abuse should not be discharged from the clinic or office without consulting the county CPS agency. The caseworker confers with the physician to determine whether the child will be safe if released to a parent or whether the child should be taken to an agency office. Ideally a caseworker should come to the hospital or office to evaluate the situation and determine the child's future safety and the need for crisis services. Children and siblings at risk for serious abuse

---

should be placed in homes of appropriate relatives or emergency receiving homes. CPS workers are expected to provide a case plan, which delineates intensive services that lead to the safe return of the child to the home if the plan is followed. CPS should complete its investigation within a reasonable stipulated time. The role of law enforcement is to perform forensic scene investigations, to interview suspects, and, if a criminal act has taken place, to inform the prosecutor's office. In most states, 48?hr after the initial report by telephone or fax by a mandated reporter, a *written* and detailed report is required. The latter is best accomplished using a printed form.

Hospital admission is indicated for children (1) whose medical or surgical condition requires inpatient management, (2) in whom the diagnosis is unclear, and (3) when no alternative safe place for custody is immediately available. If the safety of the child is in doubt, the physician, agency, and court should err on the side of protecting the child. If the parents refuse hospitalization or treatment, an emergency court order must be obtained. The parents should be told by the physician why an inflicted injury is suspected, that the physician is legally obligated to report the circumstance, that the referral is being made to protect the child, that the family will be provided with services, and that a CPS social worker and law enforcement officer will be involved. Siblings and children baby-sat by suspected abusers should have full examinations within 24?hr of the recognition of child abuse. Approximately 20% of them will be found to have signs of physical abuse. Children younger than 2 yr should have skeletal surveys.

Professionals should anticipate anger from abusing or neglectful parents; however, expressing anger in response to parental behavior damages rapport, increases defensiveness, and makes their cooperation less likely. Repeated interrogations, confrontations, and accusations may be avoided by involving CPS workers and law enforcement as a team during the investigation. If the child is hospitalized, the supervised parents should be encouraged to visit, and the hospital staff must be counseled to be courteous, helpful, and observant. The primary physician should maintain contact with the parents. An evaluation by hospital social services and pastoral care should be obtained to determine existing problems, needs, and strengths in the family. An agency caseworker and, when needed, a police officer should visit the home. A psychiatric evaluation of the parents and siblings may be indicated.

Hospitals caring for children should have a team of professionals who are trained and skilled in child abuse recognition, reporting, and services. This team should include a pediatrician, a hospital social worker, a pediatric nurse, a psychologist or psychiatrist, and a data coordinator. Roles of all team members as well as public agencies involved should be formalized in a community plan and clinical pathways. Legal and medical specialty consultants should be available. When evaluations are completed, the team should meet with the child's primary care physician, ward nurse, the CPS representative, and, as appropriate, a law enforcement officer, prosecutor, or any other member of the community agencies involved with the family to share information, clarify medical and social findings, and plan immediate and long-range goals and therapies.

Child welfare agencies are responsible for developing and monitoring a case plan for the child and family. It is important for the pediatrician to coordinate the health care of the abused child. Abused and neglected children require more intensive surveillance and well child care than do nonabused children. Placement in foster care may interrupt preventive care and treatment of acute and chronic illnesses. Because of the number of difficulties experienced by abusive families, no single agency or discipline can provide all the needed services. Services may include parent aides, homemakers, Parents Anonymous groups, telephone hotlines, environmental crisis therapy, substance abuse treatment, Big Brothers and Big Sisters, “foster” grandparents, anger management, and child-rearing counseling. Unless the parent has a serious mental illness, traditional psychotherapy, especially in isolation, may be ineffective.

Prevention.

The pediatrician's role in primary abuse prevention includes identifying parents at

high risk for being unable to accept, love, and properly discipline and care for their offspring. The history obtained from all parents should include information about pregnancy planning, pregnancy, emotional and physical health, domestic violence, and attitudes about the child and child-rearing experiences and techniques. Parental risks include a history of family violence or child abuse, drug addiction, depression, lack of support, socioeconomic problems, serious psychiatric illness, mental retardation, young parental age, closely spaced pregnancies, single-parent status of the mother, negative parental comments about the newborn infant, lack of evidence of maternal attachment, infrequent visits to a new infant whose discharge is delayed because of prematurity or illness, inappropriate anger toward or spanking of an infant younger than 18 mo or a handicapped child, and neglect of infant hygiene. The use of an instrument on any part of the body, a bruise from corporal punishment, or striking any part of the body aside from the hands or buttocks should be considered inappropriate and reportable. Child risks include mental or physical handicap, chronic illness, prematurity, being a twin, and learning or behavior problems. Abuse and serious neglect may be prevented when at-risk families receive intensive training and support during pregnancy and after delivery. Prevention efforts should include early and frequent contact between mother and baby in the delivery room, rooming-in, increased parental contact with premature infants, extra help calming the crying or "difficult" infant, more frequent office visits for at-risk infants, ongoing counseling regarding discipline and the use of nonphysical responses to behaviors, public health nurse visits or trained home visitors, parenting classes, stress and anger management classes, close follow-up of acute and chronic illnesses, telephone hotlines, arrangement for child care or preschool, and assistance in family planning.

Prognosis.

Early studies of abused children returned to their parents without any intervention indicate that about 5% are subsequently killed and that 25% are seriously re-injured. With comprehensive, intensive family treatment, 80–90% of families involved in child maltreatment may be rehabilitated to provide adequate care for their children. Approximately 10–15% of maltreating families, especially those with a history of substance abuse, can only be stabilized and will require an indefinite continuation of supporting services, which may include drug monitoring, until their children are old enough to leave home. Termination of parental rights or continued foster placement is required in 2–3% of cases. If a parent is unable to respond to a treatment plan, this should be documented as soon as possible to afford the child the opportunity to develop in a healthy and permanent home.

Children with injuries to the CNS may develop mental retardation, learning problems, behavior problems, blindness, deafness, motor problems, organic brain syndrome, seizures, hydrocephalus, and ataxia. Common emotional traits of abused children include fearfulness, aggression, hypervigilance, denial, projection, post-traumatic stress disorder (PTSD), a lack of trust, low self-esteem, juvenile delinquency, substance abuse, and hyperactivity. Unsuccessful treatment may result in children who become bullies, juvenile delinquents, violent and antisocial adults, spouse and elderly abusers, and the next generation of child abusers.

35.1 Sexual Abuse

Sexual abuse includes any activity with a child, before the age of legal consent, that is for the sexual gratification of an adult or a significantly older child. Sexual abuse includes oral-genital, genital-genital, genital-rectal, hand-genital, hand-rectal, or hand-breast contact; exposure of sexual anatomy; forced viewing of sexual anatomy; and showing of pornography to a child or using a child in the production of pornography. Sexual intercourse includes vaginal, oral, or rectal penetration. Penetration is entry into an orifice with or without tissue injury. Younger perpetrators tend to have younger victims but are more likely to have intercourse with older victims. Sex acts perpetrated by young children are learned behaviors and are associated with experiencing sexual abuse or exposure to adult sex or pornography. Without detection and intervention, sexual abuse may progress from touching to intercourse. *Sexual play,* on the other hand, may be defined as viewing or touching of the genitals, buttocks, or chest by preadolescent children separated by not more than 4 yr, in which there has been no force or coercion. See Chapter 26 for a discussion of the development of sexual identity and behavior.

Sexual mistreatment of children by family members (incest) and nonrelatives known to the child is the most common type of sexual abuse. The *least common* offender is a stranger. Intrafamilial sexual abuse is difficult to document and manage, because the child must be protected from additional abuse and coercion to not reveal or to deny the abuse while attempts are made to preserve the family unit. Children also may be coerced to recant accusations of abuse by relatives, or they may decide to recant the abuse for fear of ridicule or teasing, retaliation, attendance in court, or loss of contact with needed or loved relatives and friends.

Epidemiology.

Most of the increase in child abuse reports through 1992 were due to increased reporting of sexual abuse. The rate of sexual abuse, estimated by the American Association for Protecting Children, went from 1.4/10,000 to 17/10,000 children between 1976 and 1984. Surveys of adult women indicate that from 12–38% were sexually abused by 18 yr of age. The results of one study indicated that the likelihood of extrafamilial and intrafamilial sexual abuse being reported were 8% and 2%, respectively. The incidence of sexual abuse of males ranges from 3–9% of the population, accounting for up to 20% of reports. Because fixed pedophiles show a predilection for boys, it is theorized that the number of males who are sexually abused is higher. Furthermore, boys may refrain from reporting what they might interpret as a homosexual action or a consequence of their failure to protect themselves from assault. From 1992 to 1999, NCANDS data revealed a 39% decline in instances of substantiated cases. State officials cite the following reasons for this decline: (1) increased evidence needed for substantiation, (2) increased caseworker caution due to new legal rights of caregivers, and (3) limitations on cases accepted, effectiveness of prevention programs, and increased prosecution and public awareness. Incarceration of perpetrators and an improved economy are other theories for this decrease.

In 1997, 679 reports (71% of all abuse reports) from a children's hospital were for sexual abuse. Of 744 patients referred to a diagnostic clinic for suspected sexual abuse, 230 (31%) were reported. A lack of substantiation may be due to a child's young age and inability to give a detailed history or a lack of significant physical or laboratory findings. Caregivers may mistake genital erythema, enuresis, masturbation, or nonspecific behaviors as being due to sexual abuse. Suspicion may be increased during divorce proceedings due to distrust of the other parent and changes in the child's behavior caused by the divorce process. Approximately one third of sexual abuse victims are younger than 6 yr of age; one third are 6–12 yr of age; and one third are 12–18 yr of age. Reported offenders are 97% male. Females are more often perpetrators in child-care settings, including baby sitting. The number of female perpetrators may be higher because younger children may confuse sexual abuse by a female with normal hygiene care, and adolescent males may not be trained to recognize sexual activity with an older female as a form of abuse. Sexual abuse by stepfathers is nearly five times higher than by natural fathers. Incest is described in most cultures and is seen at all socioeconomic levels to a greater degree than are physical abuse and neglect.

Etiology.

The abuse of daughters by fathers and stepfathers is the most common form of reported incest, although brother-sister incest is considered to be the most common type. Studies of incarcerated adult perpetrators indicate that sexual abuse begins with selection of vulnerable and available victims, innocent physical contact, and seduction through gifts and attention. The propensity for pedophiles to become sexually involved with children often appears in their adolescence. Pedophiles have indicated that they seek positions and opportunities where they can be in contact with potential victims. The vulnerable children they described include those with mental and physical handicaps, unloved and unwanted children, previously abused children, children in single-parent families, children of drug abusers, their own children, and children with low self-esteem and poor achievement. Pornography may be used to initiate sexual activity with a child. Threats and bribes may be used to entice children and keep them from telling. Boys and girls may be told that they are at fault because they did not protect themselves. Care must be exercised when evaluating these data as the characteristics of incarcerated perpetrators or perpetrators in therapy, upon which many study results are based, may be different from those of other perpetrators. Obedience and trust of adults, coupled with a need to maintain family unity, are factors associated with incest. A father's need for sexual gratification and a daughter's need for affection and nurturance may lead to incest when the mother is unavailable and there is a desire to maintain the family unit. These incestuous fathers have been described as rigid, patriarchal, and emotionally immature. They are unlikely to engage in extramarital relationships, and there is a high incidence of alcoholism. The mothers have been described as chronically depressed, unavailable to their husbands because of work or illness, and often the

victims of childhood sexual abuse. The child victim tends to be pseudomature and to have taken on many of the adult roles, including housekeeping. The tendency for some of these families to be closely knit and socially isolated prevents detection.

Violence is not common in sexual abuse; however, its incidence increases with the age and size of the victim and specific traits in the perpetrator. Violence is more likely to occur in association with a single incident by a stranger. In cases of violent incest, the father has been described as sociopathic, with sexual abuse extending outside the family circle.

Clinical Manifestations.

A child may disclose sexual abuse to the mother and be brought to a physician at that time. If the mother does not believe the child, the child may delay further comment indefinitely or later tell a friend, relative, friend's mother, teacher, or school counselor. Children, given the opportunity, may disclose their abuse to a physician in a private interview or during a physical examination. Sexual abuse should be considered as the cause of physical symptoms such as (1) vaginal, penile, or rectal pain, discharge, bruising, erythema, or bleeding; (2) chronic dysuria, enuresis, constipation, or encopresis; and (3) rarely, premature puberty in a female. Certain behaviors, although more likely to be associated with sexual abuse, have not been found to be diagnostic. They include sexualized activity

with peers, animals, or objects; seductive behavior; and age-inappropriate sexual knowledge and curiosity. Nonspecific behaviors include suicide gestures, fear of an individual or place, nightmares, sleep disorders, regression, aggression, withdrawn behavior, PTSD (see Chapter 22), low self-esteem, depression, poor school performance, running away, self-mutilation, anxiety, fire setting, multiple personalities, somatization, phobias, trauma, prostitution, drug abuse, eating disorders, dysmenorrhea, and dyspareunia. Because of secrecy, a desire to protect the abuser or family, or threats by the abuser, the cause of symptoms or behaviors may be denied by the child. When the perpetrator is a breadwinner or is violent, it may also be denied by the nonoffending and dependent parent.

Investigating the possibility of sexual abuse requires supportive, sensitive, and detailed *history* taking. Because of variance in the type of abuse, the ages of the victim and perpetrator, and the time since abuse, less than 15% of cases yield physical or laboratory findings. Ideally, the videotaped forensic interview, which uses open-ended, nonleading questions, should be conducted on one occasion by one or two experienced interviewers in the presence of law enforcement and social service workers who observe behind a one-way mirror. This obviates the need for repeated interviews and possible further trauma to the child. After an initial interview, children who gain trust and comfort may experience a decrease in guilt and fear of reprisal or loss of love and give more detailed information in subsequent interviews. Interviewing should proceed at the child's pace and level of development. It should begin with discussion of general topics and naming of body parts, including “private” parts, and proceed to details about each incident. The sophistication of the information that can be obtained from the child varies with the development of the child and the skill of the interviewer. Anatomic pictures may help clarify the names of body parts and aid in describing the abuse. Anatomically correct dolls, used with young children, may be considered to be suggestive or leading. If a social worker or law enforcement officer has carried out the initial interview, the physician should review this material and decide whether it is necessary to repeat the interview before performing a physical examination. Questions about the abusive actions, including symptoms of trauma, may be asked during the physical examination. Familiarity with the child through participation in the forensic interview, a previous examination, or sick and well child care contacts facilitates a cooperative and nontraumatic physical examination.

PHYSICAL EXAMINATION.

Older female and male victims may prefer that a physician of the same sex examine them; when possible, their desires should be respected. A thorough physical *examination* should be conducted, with special attention to the neck and mouth. If present, bite marks should be measured, and wax impressions and wiping for saliva should be done to aid in identification of the perpetrator. The mouth should be examined for redness, abrasions, or purpura that may be due to recent trauma. The abdominal examination should assess the possibility of pregnancy. The rectum should be examined for signs of trauma.

A young female who is resistant despite preparation may be examined while sitting on the parent's lap. Occasionally, the child will be able to separate the labia or buttocks herself. The examination should be explained to the girl; anxiety can be reduced by distracting her. She can be asked to blow on a pinwheel, sing, or count. The female is most easily examined in the supine frog leg position. The hymen is exposed by separation of the labia laterally or by grasping the labia majora with the gloved thumbs and forefingers and gently tugging the labia toward the examiner (Fig. 35–4). This labial traction is best accomplished by an assistant while the genitals are viewed in good lighting and with magnification. If abnormalities are

Figure 35.1-4 Normal hymen. This is the hymen of an 8 yr old. The hymen opening (O) has a delicate and almost transparent edge. There is a right (r) and left (l) wall, which may vary in size from 1 to 3?mm. The base of the hymen (H) may vary from 1 to 4?mm. The term *attenuation* is applied to the base when it is less than 1?mm wide. The fourchette (F) is the joining of the labia minora posteriorly. It may be injured from trauma. The vestibule, or space anterior to the hymen which is surrounded by the labia minora, may be penetrated without damage to the hymen.

found on supine examination, the child should be re-examined in the prone knee-chest position. In that position, gravity allows better visualization of the hymen anatomy and confirmation of suspected abnormalities. There are several normal shapes to the hymen. In the infant or prepubertal child, flaps or tabs on the hymen may obscure the opening. This is rectified when drops of sterile saline are used to “float” the tabs, revealing the opening. Maternal hormones thicken the newborn's hymen in a manner similar to the effects of endogenous hormones in adolescence. As this hormone effect wanes, by 1 yr the hymen becomes thin, in some cases to the point of transparency with visible vascularity. As the hymen thickens in adolescence (Fig. 35–5), it folds on itself. This undulation makes the hymen more distendible and the examination of the hymen rim more difficult. A moist cotton swab, a swab covered with a rubber balloon or, less commonly, a Foley catheter may assist in the examination. The Foley is inserted through the hymen opening and then inflated with

saline before being drawn against the inner hymen wall. Opening size of the hymen is not considered of diagnostic value. The examination of the hymen, which is facilitated by the use of magnification and proper lighting from a colposcope, should include inspection of the fourchette, the introitus, the urethra, and the edge of the hymen. A speculum examination of the vagina with collection of specimens is indicated when the victim is postpubertal or when nonmenstrual vaginal bleeding or major trauma of the external genitals is present. No child should be forced to have an examination. General anesthesia or sedation may be required if the examination is deemed necessary or if there is bleeding from the rectum or vagina.

Drawings of trauma should be supplemented with photographs or video recordings using the colposcope or photos from a hand-held analog or digital camera with a macro lens. “Suggestive findings” or findings in keeping with a history of

Figure 35.1-5 Hymen with estrogen effects and wart. With the onset of puberty, the hymen becomes thickened, paler in color, and redundant. The resulting folds make it difficult to determine whether there are abnormalities of the edge of the hymen. The *arrow* points to a glistening bump on the left hymen wall. This is a venereal wart. The appearance of these warts varies with location. Other warts on the skin surface were dark in color with an irregular “cauliflower-like” appearance.

Figure 35.1-6 Hymen tear. The base (*arrow*) of the hymen has been torn to the floor of the vagina. The injury, from finger insertion according to the 8-year-old child, is bleeding. The fourchette (F) has escaped injury. Careful observation may reveal complete healing of the injury over time. The tear also may heal with a V-shaped notch, or remain separated.

sexual abuse include (1) a hymen with new or healed lacerations and transections (Fig. 35–6), remnants, and attenuation; (2) posterior fourchette lacerations; (3) vaginal wall tears; and (4) perianal lacerations. The presence of sperm and semen is “clear evidence” of sexual abuse. Other suggestive findings include bite marks on the genitals or inner thigh or scarring or tears of the labia minora. Straddle injuries usually result in trauma to the labia and clitoris and rarely involve the relatively protected hymen. Accidental penetration of the hymen is unusual and is associated with penetration of underclothing and possibly the wall of the vagina.

Abnormal findings even with a history of repeated anal penetration are unusual. A fissure can result from the insertion of an object larger than the child's normal stool. The use of lubrication may minimize penetration damage. Frequent passage or insertion of a dilating object can result in decreased anal tone and changes in the appearance of anal folds. Examination by an experienced professional, with photo documentation, is necessary if there are any questions about anogenital findings. If immediate dilation of the anus reveals an anterior-posterior diameter greater than 20?mm, with no stool present in the rectal ampulla, that is a strong marker for possible abuse, warranting further investigation. Scar formation, even following an episode of forceful sodomy, is unusual. There are two common, midline, naturally occurring entities that may be confused with scar tissue in the perianal region. The first is a smooth, wedged-shaped area known as *diastasis ani*. This can be found either anterior or posterior to the anus. The second finding is an extension of the median or perineal raphe that has a taglike appearance on the anterior side of the anus. Anal fissures, decreased anal tone, or disruption of folds must be interpreted with caution, because they can be the result of chronic constipation or underlying disease, such as Crohn disease.

Injuries to the male genitals are usually the result of an accident or physical abuse. A bite mark may be found. The forceful retraction of the foreskin may result in a dehiscence of the tissues. Injury from a sexual assault most likely causes a nonspecific, transitory redness of the penis. Routine examination of the genitals of males and females facilitates recognition of normal findings and helps guarantee future cooperation from the child.

Laboratory Findings.

Laboratory investigation depends on the history and the time since injury. When a victim is seen within 72?hr of sexual abuse, clothing and skin should be swabbed with a moist cotton applicator. A variety of substances, including urine, fluoresce under a Wood lamp. In addition, specimens of possible offender blood and hair and the victim's nail clippings and clothing should be collected. Tests for rectal blood may be indicated. If there is a history of contact with the perpetrator's genitals, gonorrhea and *Chlamydia* cultures should be obtained from the mouth, anus, and genitals. In the vagina, motile sperm can be found for 6?hr; nonmotile sperm exist for longer than 72?hr. Acid phosphatase is present for 24?hr. Sperm and semen may also be recovered from the mouth, rectum, and clothing. Although the presence of semen substantiates the victim's history of vaginal intercourse, the absence of semen does not contradict it. Less than 5% of victims have positive cultures for gonorrhea or *Chlamydia*. Symptomatic victims, those with positive cultures for other venereal diseases, and children with a history of contact with the perpetrator's genitals should also be tested for syphilis, HIV, and hepatitis B. All specimens should be transferred to the forensic laboratory in sealed, signed, and dated envelopes to ensure an official chain of evidence.

Diagnosis.

It is most common for the diagnosis of sexual abuse to depend on the history offered by the victim. False accusations are rare except in unusual cases involving adolescents,

emotionally disturbed patients, or patients in custody disputes. Abuse may be revealed during a custody dispute because the child has been separated from an offender and is able to communicate without fear of retaliation or further abuse. The genitals and rectum may heal completely after extensive trauma, and minor trauma, such as abrasions, may heal within 3–4 days. The tear may remain separated, heal to the point where it cannot be easily differentiated from normal, or heal with a V-shaped notch (see Fig. 35–6). Healing depends on the degree of trauma; however, the most severe trauma, requiring surgical repair, may appear normal after a year or less. There may be no observable physical trauma in as many as 85% of children who report sexual abuse. The anus or vagina may not be penetrated, although there is pain experienced. Superficial injuries such as abrasions or

erythema heal in days with no lasting signs. Certain types of sexual abuse such as oral or digital stimulation or labial intercourse may not result in tissue damage. If an inserted object is smaller than the expanded size of an opening, no tissue damage would be expected. The data from an interview by a professional trained and experienced in forensic interviewing techniques should not be minimized because there are no physical findings. In one study of 18 victims whose abusers confessed to vaginal penetration, seven children had normal genital examination findings. Abnormal physical or laboratory findings should be reported even if no history is available.

Laboratory findings of pregnancy, sperm, semen, and *nonpregnancy-* or *delivery-related* syphilis, gonorrhea, *Chlamydia*, herpes type II (genital), and HIV may be considered diagnostic of sexual abuse and reported. Condyloma acuminatum appearing after 3 yr of age and *Trichomonas vaginalis* are considered "probably diagnostic." Herpes type I and nonvenereal warts may be autoinoculated to the genitorectal area or transmitted by a perpetrator's mouth or hand. The significance of bacterial vaginosis and genital *Mycoplasma* infection is uncertain. New techniques, such as DNA typing of blood, semen, sperm, or tissue, may positively identify the perpetrator.

Treatment.

Sexual abuse is a criminal offense and is investigated by the police. All victims of sexual abuse require psychologic support. Parents, relatives, and siblings may deny the accusation and rebuke or punish the child for reporting the incident. The consequences and appropriate therapy of sexual abuse vary, depending on the type of abuse, the age and other physical and emotional factors in the victim, the frequency of abuse, and the identity of the abuser. Victims of a single nonviolent episode of touching or exposure by a stranger may require reassurance and a chance to express feelings about the event in one or two therapy sessions. Victims may be less distressed by the incident than their parents. In contrast, a single episode of family-related sexual abuse may cause serious, long-term emotional distress and require prolonged individual and group treatment. The therapist may recommend that the victim of incest be returned home if the perpetrator is out of the home or has confessed and is in therapy. The child victim should be placed in foster care if this is his or her desire; if the nonoffending parent is not protective of the child, does not believe the child's story, or is likely to encourage the child to recant; and if family life is chaotic or collection of evidence is not yet complete. Medication to prevent pregnancy may be given to postmenarchal girls in midcycle who have experienced vaginal intercourse within the previous 72?hr. Treatment with antibiotics is initiated to prevent sexually transmitted disease if the perpetrator is known to be infected, if the victim has signs of infection, or if the likelihood of follow-up is poor. All victims should revisit their primary care physicians within 2 wk to ensure that recommended services have been implemented.

Incest offenders may respond to treatment, but success requires a coordinated, multifaceted, multidisciplinary approach. The offending parent and spouse should be referred for psychiatric or psychologic evaluation. The police should investigate offenders, and criminal prosecution should be supported. There is evidence, especially in pedophilia, that incarceration may ensure access to, and efficacy of, simultaneous treatment. Incarceration of a breadwinner may have serious adverse consequences for the family. The behavior of chronic sexual offenders may be resistant to a variety of therapies. All juvenile and prejuvenile offenders should receive therapy to prevent recurrences. In one diagnostic center, 17% of offenders were younger than 17 yr of age.

Prevention.

The primary prevention of sexual abuse is related, in part, to normal developmental education and sexual behavior (Chapter 26). Teaching children the proper names of all body parts, including the names, function, and significance of "private parts" (nipples, genitals, and rectum) should begin in the home and continue in the pediatrician's office and school. Children should be taught to say "no" to any action by any person that makes them uncomfortable—but especially actions directed to their "private" areas. They should be given the opportunity to report to a trusted adult any of these actions. Caregivers, including baby sitters and their companions and the boyfriends of single mothers, should be carefully screened. Written permission should be obtained from any caregiver to allow a police screening for offenses. Victim therapy should decrease the potential for re-abuse. Routine family and classroom discussions of uncomfortable events in the lives of children may reveal unsuspected abuse. To improve diagnostic skills, physicians should examine the genitals and rectum routinely, record their findings, become familiar with normal rectal and genital anatomy and the consequences of trauma, listen to and seriously consider what children tell them, and be willing to report and testify when abuse is suspected.

Prognosis.

With early and adequate intervention, victims may lead normal adult lives. However, even with intervention, certain adolescent victims may run away from home and fall prey to adolescent prostitution, violence, drug addiction, and unprepared parenthood (see Chapter 39). Others who remain at home may manifest a variety of emotional problems, including depression, suicidal gestures, deterioration in school performance, and conversion reactions. As adults, victims may have difficulties with close relationships; enter abusive relationships; have a variety of somatic complaints of the genitourinary, gastrointestinal, and other systems; and need psychiatric help for depression, anxiety, substance abuse, dissociation, and eating disorders. The risk of untoward effects is greatest for incest victims.

35.2 Nonorganic Failure to Thrive

See Chapter 36 for a full discussion of organic and nonorganic failure to thrive (NOFTT). NOFTT occurs when a child, usually an infant, is not fed adequate calories. The mother may neglect proper feeding because she is involved with external demands and the care of others; is preoccupied with inner problems or depressed; is ignorant about appropriate feeding; is abusing substances; or does not like or understand the infant. Emotional or maternal deprivation is inevitably concurrent with nutritional deprivation. These mothers often feel deprived and unloved themselves and may be acutely or chronically depressed. Multiple and continuing crises, frequently compounded by the physical absence of the father, may overwhelm a mother,

who reacts by neglecting her infant. Poverty may also prevent a caregiver from obtaining adequate food for a child. Retarded and emotionally disturbed parents may not have the capacity to provide proper care.

Clinical Manifestations.

The dietary history in infants with nutritional neglect may not be accurate because the parent misinforms the physician that the baby is receiving adequate calories. Depending on severity, the infant with NOFTT may exhibit thin extremities, a narrow face, prominent ribs, and wasted buttocks. Neglect of hygiene is evidenced by diaper rash, unwashed skin, untreated impetigo, uncut and dirty fingernails, or unwashed clothing. A flattened occiput with hair loss may indicate that the child has been lying on his or her back. This flattening may be due to being unattended for prolonged periods or positioning to prevent SIDS. Delays in social and speech development are common. Other findings include an avoidance of eye contact, an expressionless face, and the absence of a cuddling response. The amount of time that the mother spends holding, playing with, and talking to her baby is usually reduced or inappropriate. A rejecting or frustrated mother may feed her baby with anger and unnecessary force. This may result in a torn frenulum and an aversion to feeding. Children of all ages may fail to thrive because of intentional or nonintentional malnutrition.

Laboratory Findings.

Extensive laboratory evaluation should be delayed until dietary management has been attempted for at least 1 wk and has failed. A skeletal survey is indicated in children younger than 2 yr who have a rejecting parent or evidence of associated physical abuse.

Diagnosis.

Children with NOFTT should be hospitalized and given unlimited feedings of a diet appropriate for age for a minimum of 1 wk; this diet usually approaches 150?kcal/kg (ideal weight)/24?hr. Infants with NOFTT usually gain more than 2 oz every 24?hr for 1 wk (approximately 1?lb/wk) or have a gain that is significantly greater than that achieved during a similar period at home. These infants may display a ravenous appetite. A nursing plan should include careful charting of intake, weight, and observations of the mother's feeding style and relationship to the child. The latter may be videotaped for analysis. Deprivational behaviors may improve or resolve in the hospital setting with attention from the staff. Infants who are difficult to feed because of neurologic or mechanical problems may gain weight as a result of the intensive efforts by experienced hospital staff.

Treatment.

All cases of NOFTT caused by underfeeding from maternal neglect should be reported to CPS. After appropriate hospital management, approximately 75% of infants are discharged home with added services for the family; 20% go into temporary foster care while the parents receive therapy; and 5% enter long-term foster care with plans for voluntary relinquishment or termination of parental rights. Exercising this last option should be based mainly on the responsiveness of the mother to treatment. Infants who are discharged to their natural home require intensive and long-term intervention. The parents should be provided with clear, written dietary instructions at discharge and be trained to hold the infant close during feedings and to provide frequent and appropriate stimulation. Families may require a homemaker, public health nurse, health visitor, and other types of outreach services. Weekly medical follow-up is necessary to monitor progress.

Prognosis.

Without detection and intervention, a small percentage of infants with nutritional neglect die of starvation. Approximately 5–15% of these infants suffer from physical abuse. Weight loss and understature from malnutrition are reversible, but normal head circumference and brain growth may not be achieved if the infant has suffered from NOFTT beyond 6 mo of age. Emotional and educational problems occur in more than half these children.

35.3 Munchausen Syndrome by Proxy (MSBP)

The term *Munchausen syndrome* was used initially to describe situations in which adults falsified their own symptoms. In MSBP, a parent, invariably the mother, simulates or causes disease in a child. The parent may (1) fabricate a medical history; (2) cause symptoms by repeatedly exposing the child to a toxin, medication, infectious agent, or physical trauma, including smothering; or (3) alter laboratory samples or temperature measurements. Depending on the parent's sophistication and secrecy, a variety of convincing, novel, and exotic diseases may be simulated or created. The parent may deny any involvement and, in instances of intentional poisoning, smothering, or trauma, may continue the action while the child is hospitalized. Parents of children hospitalized for evaluation of acute life-threatening events have been videotaped in the process of smothering their children. MSBP is inflicted on children who are either unable or unwilling to identify the true offense and offender. The abusing caregiver gains attention from the relationships formed with health care providers or her own family as a result of the problems created.

Clinical Manifestations.

The child's symptoms, their pattern, or the response to treatment may not be compatible with a recognized disease. They may involve any organ system and suggest a panoply of disease processes. Although generally reported in preverbal children, cases have been recognized in children up to 16 yr of age. There may be a history of actual disease in which symptoms persist beyond the time when cure is anticipated. Symptoms in younger children are always associated with the proximity of the mother to the child. The mother may have a background in health care, may be supported by the father who may be unavailable, and may present as a devoted and model parent who forms close relationships with members of the health care team. She may have a history of Munchausen syndrome (MS) and seem relatively unconcerned about the severity of the child's illness.

Apnea and seizures are two common manifestations of MSBP. The observation may be falsified or may be created by partial suffocation. Symptoms also can be created by toxins, medications, water, and salts. Recognition of MSBP requires familiarity with those substances available to families and the wide array of consequences from misuse of these substances. The clinical pattern is variable, depending on the agent. It includes forced ingestion of medications such as ipecac to cause chronic vomiting or laxatives to cause diarrhea, or injection of insulin with consequent seizures. The skin, which is more easily accessible to the perpetrator, may be burned, dyed, tattooed, lacerated, or punctured to simulate acute or chronic skin conditions. Infectious or toxic agents may be administered into any available orifice. Provision of intravenous lines during hospitalization may provide an opportunity for injection of

infectious agents from feces, toxins, and pharmacologic agents. Urine and

blood samples may be contaminated with foreign blood or stool. Older children may become convinced that they have an illness and dependent on the increased attention attendant upon the situation. This may lead to the child feigning symptoms or to MS.

Diagnosis.

Investigations should be based on a high index of suspicion of this diagnosis so that unpleasant, dangerous, or unnecessary tests are not undertaken on the child. Specimens that are carefully collected should be analyzed for potentially harmful agents and for “foreign” blood. All steps in the diagnosis should be carefully documented. Records from other hospitals for the index child and siblings should be obtained and carefully reviewed. Hospitalized children should be under constant surveillance. This may include hidden television monitoring in coordination with law enforcement. Frequent staff meetings with detailed minutes are necessary to ensure that all information is gathered and recorded in a planned and forensic manner.

Treatment.

After all laboratory information is collected and the diagnosis is established, the offending parent should be confronted by a nonaccusatory physician and staff who offer help. Any approach may be met with resistance, denial, and threats. All cases should be reported promptly and with careful documentation to CPS. The consequences of MSBP include persistence of abuse, emotional problems, chronic disability in 8% of cases, and death. Other siblings may be, or may have been, at risk; there is an association of this syndrome with unexplained infant deaths.

Part 5 - Children with Special Health Needs

Chapter 36 - Failure to Thrive

Howard Bauchner

Failure to thrive (FTT) is diagnosed in an infant or child whose physical growth is significantly less than that of his or her peers, and it is often associated with poor developmental and cognitive functioning. Although there is no clear consensus definition, FTT usually refers to growth below the 3rd or 5th percentile or a change in growth that has crossed two major growth percentiles (i.e., from above the 75th percentile to below the 25th) in a short time. Traditionally, FTT was considered either organic or nonorganic. Organic FTT is marked by an underlying medical condition; nonorganic or psychosocial FTT occurs in a child who is usually younger than age 5 yr and has no known medical condition that causes poor growth (also see Chapter 35.2).

Epidemiology and Etiology.

The prevalence of FTT depends on the population sampled. From 5–10% of low-birthweight children and children living in poverty may have FTT. Family dysfunction, neonatal problems other than low birthweight, and maternal depression are also associated with FTT. In the United States, psychosocial FTT is far more common than organic FTT.

The causes of organic FTT are numerous (Table 36–1). Every organ system is represented. Psychosocial FTT is most often due to poverty or poor child-parent interaction. It occasionally occurs with severe stress such as child abuse. Organic and nonorganic etiologic factors may also occur together, for example, in children who are victims of abuse and neglect or temperamentally difficult premature infants.

Clinical Manifestations.

The clinical presentation of FTT ranges from failure to meet expected age norms for height and weight, to alopecia, loss of subcutaneous fat, reduced muscle mass, dermatitis, recurrent infections, marasmus, and kwashiorkor. In developed countries, the most common presentation is poor growth detected in an ambulatory setting; in developing countries, recurrent infections, marasmus, and kwashiorkor are more common presentations.

The degree of FTT is usually measured by calculating each growth parameter (weight, height, and weight/height ratio) as a percentage of the median value for age based on appropriate growth charts. Appropriate growth charts are often not available for children with specific medical problems; serial measurements are especially important for these children. For premature infants, correction must be made for the extent of prematurity. Corrected age, rather than chronologic age, should be used in calculations of their growth percentiles until 1–2 yr of corrected age.

For weight, mild, moderate, and severe FTT is equivalent to 75–90%, 60–74%, and less than 60% of standard, respectively. For height, the corresponding values are 90–95%, 85–89%, and less than 85%. For the weight/height ratio, the values are 81–90%, 70–80%, and less than 70%. The weight for age per cent of the standard value traditionally decreases early in the course of FTT, followed by a decrement of height for age. Children with chronic malnutrition often have a normal weight for height because both their weight and height are reduced.

The laboratory evaluation of children with FTT is often not helpful and, therefore, should be used judiciously. A complete blood count, lead level, and urinalysis represent a reasonable initial screen. Bone age is often helpful in distinguishing family short stature (bone age equivalent to chronological age) from endocrine or nutritional abnormalities (bone age is less than chronological age). Other tests, such as thyroid function studies, tests for gastroesophageal reflux and malabsorption, organic and amino acids, or a sweat test, should be performed if indicated by the history or physical examination.

Diagnosis.

The history, physical examination, and observation of the parent-child interaction usually suggest the diagnosis. The latter observation, especially with feeding, is often critical to the diagnosis of psychosocial FTT.

The causes of insufficient growth include (1) failure of a parent to offer adequate calories, (2) failure of the child to take sufficient calories, and (3) failure of the child to retain sufficient calories. Reasons why parents or other caregivers may not offer appropriate or sufficient foods include lack of knowledge, parental depression, unusual dietary beliefs, or lack of food. With young infants, it is particularly important to obtain a detailed dietary history, including what the diet consists of, how often the infant is fed, and how the parents respond when the child cries or sleeps for prolonged periods. Children may have difficulty swallowing if they have oral-motor dysfunction, anatomic abnormalities, cardiopulmonary dysfunction, or enlarged and recurrently infected tonsils and adenoids. Vomiting, diarrhea, and malabsorption are general causes of inadequate caloric absorption. It may be helpful to approach the diagnosis in terms of age (Table 36–2) or signs and symptoms (Table 36–3).

Treatment.

The treatment of FTT requires an understanding of all the elements that contribute to a child's growth: a child's health and nutritional status, family issues, and the parent-child interaction. Regardless of cause, an appropriate feeding atmosphere at home is important. Children with severe malnutrition must be re-fed carefully.

For children with organic FTT, the underlying medical condition should be treated. The type of caloric supplementation must be based on the severity of FTT and the underlying medical condition. For example, in children with renal failure, the amount of protein in the diet must be carefully monitored. The response to caloric supplementation depends on the specific diagnosis, medical treatment, and severity of FTT.

For older infants and young children with psychosocial FTT, mealtimes should be approximately 20–30?min, solid foods should be offered before liquids, environmental distractions should be minimized, and children should eat with other people and not be force fed. The intake of water, juice, and low-calorie beverages should be limited. High-calorie foods, such as peanut butter, whole milk, cheese, and dried fruits, should be emphasized. High-calorie supplementation, such as Duocal or Polycose, or high-calorie liquids, such as Carnation Instant Breakfast with whole milk, or formulas containing more than 20 calories per ounce (PediaSure, Ensure, and Resource) are sometimes necessary. Weight gain in response to adequate caloric feedings usually establishes the diagnosis of psychosocial FTT.

TABLE 36-1 -- **Major Organic Causes of Failure to Thrive**

System	Cause
Gastrointestinal	Gastroesophageal reflux, celiac disease, pyloric stenosis, cleft palate/cleft lip, lactose intolerance, Hirschsprung's disease, milk protein intolerance, hepatitis, cirrhosis, pancreatic insufficiency, biliary disease, inflammatory bowel disease, malabsorption, food alkalines
Renal	Urinary tract infection, renal tubular acidosis, diabetes insipidus, chronic renal insufficiency
Cardiopulmonary	Cardiac diseases leading to congestive heart failure, asthma, bronchopulmonary dysplasia, cystic fibrosis, anatomic abnormalities of the upper airway, obstructive sleep apnea (snoring)

Endocrine	Hypothyroidism, diabetes mellitus, adrenal insufficiency or excess, parathyroid disorders, pituitary disorders, growth hormone deficiency
Neurologic	Mental retardation, cerebral hemorrhages, degenerative disorders
Infectious	Parasitic or bacterial infections of the gastrointestinal tract, tuberculosis, human immunodeficiency virus disease
Metabolic	Inborn errors of metabolism
Congenital	Chromosomal abnormalities, congenital syndromes (fetal alcohol syndrome), perinatal infections
Miscellaneous	Lead poisoning, malignancy, collagen vascular disease, recurrently infected adenoids and tonsils

TABLE 36-2 -- **Approach to Failure to Thrive Based on Age**

Age of Onset	Major Diagnostic Consideration
Birth to 3 mo	Psychosocial failure to thrive, perinatal infections, gastroesophageal reflux, inborn errors of metabolism, cystic fibrosis
3–6 mo	Psychosocial failure to thrive, human immunodeficiency virus infection, gastroesophageal reflux, inborn errors of metabolism, milk protein intolerance, cystic fibrosis, renal tubular acidosis
7–12 mo	Psychosocial failure to thrive (autonomy struggles), delayed introduction of solids, gastroesophageal reflux, intestinal parasites, renal tubular acidosis
12 + mo	Psychosocial failure to thrive (coercive feeding, new psychologic stressor), gastroesophageal reflux

Adapted from Frank D, Silva M, Needlman R: Failure to thrive: Mystery, myth and method. Contemporary Pediatrics 1993;10:114.

TABLE 36-3 -- **Approach to Failure to Thrive Based on Signs and Symptoms**

History/Physical Examination	Diagnostic Consideration
Spitting, vomiting, food refusal	Gastroesophageal reflux, chronic tonsillitis, food allergies
Diarrhea, fatty stools	Malabsorption, intestinal parasites, milk protein intolerance
Snoring, mouth breathing, enlarged tonsils	Adenoid hypertrophy, obstructive sleep apnea
Recurrent wheezing, pulmonary infections	Asthma, aspiration
Recurrent infections	Human immunodeficiency virus disease
Travel to/from developing countries	Parasitic or bacterial infections of the gastrointestinal tract

Adapted from Frank D, Silva M, Needlman R: Failure to thrive: Mystery, myth and method. Contemporary Pediatrics 1993;10:114.

Indications for hospitalization include severe malnutrition, further diagnostic and laboratory evaluation, lack of catch-up growth, and evaluation of the parent-child feeding interaction. Parents of children with organic FTT should be comfortable with the diagnosis and treatment before discharge. For psychosocial FTT, hospitalization often lasts 5–10 days. Caloric intake should be monitored, and the parent-child feeding interaction should be observed (Chapter 35.2). The goals of hospitalization are to obtain sustained catch-up growth and educate parents about appropriate foods and feeding styles. For both organic and psychosocial FTT, the approach to feeding in the hospital should mimic the anticipated treatment at home before discharge.

Prognosis.

FTT in the 1st yr of life, regardless of cause, is particularly ominous. Maximal postnatal brain growth occurs during the first 6 mo of life. The brain grows as much during the 1st yr of life as during the rest of a child's life. Approximately one third of children with psychosocial FTT are developmentally delayed and have social and emotional problems. The prognosis for children with organic FTT is more variable, depending on the specific diagnosis and severity of FTT. Ongoing assessment and monitoring of cognitive and emotional development, with appropriate intervention, is necessary for all children with FTT.

Chapter 37 - Developmental Disabilities and Chronic Illness

James M. Perrin

Overview.

Children having special health care needs constitute a heterogeneous population that includes youngsters with a wide variety of developmental disabilities and chronic illnesses. A core of basic considerations applies to most children with chronic conditions, and these issues are discussed first.

Early detection of persistent conditions, amelioration of the functional consequences of specific disabilities, and prevention of secondary psychosocial handicaps are central to the provision of care for children with special health needs. Caregivers should recognize the importance of treating the whole child in a family and community context. Physicians occasionally and inappropriately refer to children with chronic conditions by the name of their condition, such as “asthmatics,” “sicklers,” “leukemics,” or “Down's babies.” This tendency to characterize children by their disease or disability adversely influences both parental and professional attitudes as well as objective assessments of the child's current abilities and expectations for the future. In general, parents and professionals should work together on behalf of a child who has a disease rather than allowing the disease to define the child.

Most children receive the majority of their health care from a single physician and are educated in regular school settings that require no modifications to meet special developmental or health concerns. Children having special health needs, on the other hand, may see a variety of physician specialists (e.g., neurologists, orthopedists, cardiologists), interact with multiple professionals (e.g., occupational therapists, respiratory therapists, nutritionists, psychologists), and need major adaptive modifications in their school setting (e.g., barrier-free facilities, special education services, and specialized nursing care). Some of these services, especially those of pediatric subspecialists, are provided in hospital-based programs; others, such as home health care and certain supportive therapies, may be offered in community settings. Thus, the pediatrician needs a working knowledge of community

services available to families and should help coordinate the subspecialty services received.

An appreciation of the multiple levels at which prevention or treatment efforts can be implemented requires an understanding of the differences inherent in the concepts of disease, functional limitation, and disability or social impact. Disease refers to a specific health condition affecting a child, such as arthritis or congenital cytomegalovirus infection. Functional limitation refers to the problem brought about as a result of the symptoms of the disease, such as a poorly functioning knee or a hearing impairment. Social impact (disability), on the other hand, refers to the social consequences of having the disease, such as the inability to participate competitively in sports or the social isolation that results from difficulty in communicating orally. The child's environment greatly influences these social consequences. Physicians can play a key role in preventing the occurrence of many special health needs and in diminishing their impact on a child's growth and development. Intervention may be targeted at the level of the disease, the functional limitation, or the disability. For the child with arthritis, efforts are directed both toward reducing joint inflammation and toward removing barriers to participation in age-appropriate physical activities.

Several public programs in the United States assist families of children with special health needs. In addition, parent groups in many communities help parents learn effective techniques for caring for children with chronic conditions and for obtaining the necessary health and educational services. Title V Maternal and Child Health Programs for Children with Special Health Needs provide a variety of coordinating and multidisciplinary clinical services for children who have chronic illnesses and developmental disabilities. The Individuals with Disability Education Act (IDEA) supports state-sponsored early intervention and special education programs and mandates an appropriate education in the least restrictive environment for children with disabilities. The Supplemental Security Income (SSI) program provides cash benefits for families whose children have severe physical, mental, or developmental disabilities as well as public health insurance coverage (i.e., Medicaid) in almost every state.

For children younger than age 3 yr, early intervention (EI) programs provide a mechanism for decreasing the impact of special health or developmental needs on children and their families. EI programs that incorporate the best practices offer individualized services designed to strengthen the inherent adaptiveness of participating children and families. Older children also may need special education evaluations and services or special adaptations to maximize their school attendance. Because of their strategic relationship with young children and their parents, pediatricians have an important responsibility with regard to early identification of children at risk and referral to the appropriate services (see also Chapter 5). This responsibility includes maintaining accurate and updated information on all available resources within a community to ensure that families have access to a full range of needed services. Except in the hospital, a child's family provides most care; at times, this involves an extraordinary amount of extra caretaking. Parental health, mental health, and well-being strongly affect child health outcomes in the context of disability. The best predictors of the well-being of children with special health needs include factors that relate to family health and functioning; effective pediatric management should therefore embody a comprehensive approach to the child in the context of the family, addressing the needs of all its members.

Despite the variations among conditions and their clinical requirements, families caring for children with any of these long-term conditions typically face key times of transition when additional community and health services may be necessary to improve child and adolescent functioning. This is especially the case at discharge from hospital to home after a long and complex intensive care experience or other management related to the initial diagnosis. Many families initially rely on hospital-based services to provide a wide range of therapies and now must take on responsibilities for home care, including providing services themselves and coordinating services from a variety of therapists in the home setting. Although discharge plans from hospital-based services may work well in the first few months, as nurses and equipment vendors change and as parents increasingly develop their own skills, the new arrangement needs ongoing monitoring and help. A second period of difficult transition for families is at entry to school, where the management of the child's health condition (medications and other specialized services) and plans for emergencies necessitate cooperation of school personnel. Clinicians can help ensure both the child's integration into school and the availability of school services and plans appropriate to his or her needs. A third time of transition is at adolescence. Many chronic conditions delay onset of puberty or affect cognitive abilities and make many aspects of adolescent life particularly complex. Chronic conditions may influence the ways of approaching risk-taking behaviors, substance and drug use, or the development of healthy sexuality. Families may need support and advice from clinicians during their child's adolescence. Finally, the transition to adulthood of adolescents with disabilities is critical because of difficulties in obtaining health insurance, gaining access to educational and vocational services, shifting from pediatric and adolescent care to adult health services, and achieving personal and economic independence.

37.1 Chronic Illness in Childhood

James M. Perrin

Epidemiology, Severity, and Outcome.

The *epidemiology* of chronic illness in childhood differs in important ways from that of long-term illness in adults. Adults face a relatively small number of common chronic conditions (e.g., diabetes, osteoarthritis, coronary artery disease) and few rare diseases. Children, in contrast,

---

face a wide variety of mainly quite rare diseases. Only a few groups of chronic conditions in childhood are common: allergic disorders (mainly asthma, eczema, and hay fever), neurologic disorders (mainly seizure disorders and neuromuscular conditions such as cerebral palsy), obesity, and mental health conditions (especially, attention-deficit/hyperactivity disorder and depression). Other conditions often thought to be common, such as type 1 diabetes, occur in only about 1 in 1,000 children younger than 16 yr, a much lower rate than is seen in adults. Many of the conditions described in this textbook occur with a frequency of much less than 1/1,000.

These epidemiologic distinctions have implications for both physicians and families. The adult pattern means that health care providers for adults have frequent daily experience with the common chronic illnesses of adults, remaining current and knowledgeable about such conditions as hypertension. Similarly, an adult who has been newly diagnosed with high blood pressure probably knows something about the disease and has friends or family members with hypertension. The practicing pediatrician, however, may see a new case of a malignancy only once in a decade and will make the diagnosis of cystic fibrosis or even diabetes infrequently. A family whose child has been newly diagnosed with a rare condition may never even have heard the name of the disease prior to its onset in their child. These epidemiologic facts mean that pediatricians have a difficult task in identifying children with rare conditions and in staying current with applicable technologies.

Although estimates of the size of this population vary greatly (partly because of the wide spectrum of severity of various conditions), data from the 1994–1995 National Health Interview Survey indicate that 15–18% of children and adolescents have some form of chronic condition, including physical conditions, developmental disabilities, disorders of learning, and primary mental health conditions. Adding speech defects, visual and hearing impairments, repeated ear infections, skin allergies, and other common conditions raises the prevalence to over 30%. Approximately 6–7% of all children and adolescents have some limitation of activity owing to a chronic health condition, and 1–2% have conditions severe enough to meet the very restricted definition of disability used by the federal SSI program, which is the main cash support program in the United States for people of all ages with disabling conditions. Within these groups, approximately 40% of children have disorders of development and learning; 35%, chronic physical conditions; and 25%, chronic mental health conditions. With improvements in health care and access to services in the last few decades, almost all these children and adolescents survive to adulthood, although often with major physical or psychologic problems related to their condition.

Severity is difficult to measure in most chronic illnesses. Although new techniques increasingly define the underlying genetic and molecular basis for many conditions, these biologic markers do not commonly correlate well with clinical indicators of severity, likely because a number of other genes and environmental factors affect the expression of the condition. Most measures of severity (e.g., asthma rating scales or hemoglobin A_{1C} in diabetes) reflect the interaction of biologic susceptibility, treatment, and other environmental factors. The effect of the condition on the child's development (cognitive, behavioral, and physical) and on functioning with friends or in school is another aspect of severity. Although this chapter focuses on health conditions that physiologically are relatively severe, many of the issues discussed affect children with milder conditions. Further, one type of severity (e.g., physiologic or clinical) may correlate poorly with others (e.g., psychologic or functional).

The percentage of children with severe, long-term illnesses has more than doubled in the past 2 decades, and at least 90% of these children survive to young adulthood. Changes in prevalence reflect major advances in the technology of medical and surgical care and substantial improvements in survival as well as marked increase in rates of certain chronic conditions (e.g., asthma, obesity, and mental health conditions). Rates of a few other conditions of much lower prevalence also have increased in recent years, including AIDS, the after-effects of fetal substance exposure, and major pulmonary or neurologic disease in children leaving neonatal intensive care units; however, these increases account for a very small proportion of all chronic illness in children. New genetic techniques have allowed the prenatal and preconception diagnosis of increasing numbers of certain health conditions, and genetic counseling and other interventions have diminished the incidence of other diseases.

Issues Common to Diverse Chronic Conditions.

Health care providers typically view each chronic illness as a distinct and separate entity that has its own etiology, natural history, treatment, complications, and physiologic impact. However, families of children with a variety of long-term illnesses face several issues in common, reflecting chronicity itself rather than aspects of the specific disease.

Many chronic childhood illnesses are *high-cost health conditions.* A small percentage of children with major chronic illnesses utilize a large proportion of the child health dollar; 2–4% of children with severe long-term illnesses account for at least 35% of all child health expenditures. These figures reflect only what is paid by public or

private insurance. Families face many other expenses, such as the costs of transportation, long-distance phone calls, and special diets, few of which may be reimbursed. Furthermore, chronic illness in a child makes it more difficult for both parents to work outside the home, thereby diminishing the family's financial resources.

The *daily burden of care rests mainly with the families*, and that burden can be extensive, as with a family with two teenagers with muscular dystrophy, both wheelchair-bound and requiring transportation from place to place, or with a youngster with cystic fibrosis who needs time-consuming pulmonary care prior to leaving for school each day. These daily burdens greatly extend the work of families.

Whereas most children require only a single provider for most of their health care and supervision, *children with long-term health conditions frequently have multiple providers and multiple treatments*. A child with hemophilia may have contact with a hematologist, a pediatrician, a specialized dentist, an orthopedist, a hematology nurse, a physical therapist, a psychologist, and a social worker, among others. The recommendations of any member of this group may vary from those of another, and families must often choose among conflicting advice. Clinically, there usually are tradeoffs among the choices, such as the optimal time to do a surgical procedure or the balance between seizure control and alertness. Pediatricians can help families make informed choices.

The comparative rarity of most childhood chronic conditions makes *families feel isolated*. They often wonder why they have been singled out by an unusual condition, and they feel that no other families have had similar experiences. Family programs in specialty centers (e.g., cystic fibrosis or arthritis centers) and parent advocacy programs have worked to break this sense of isolation through groups that help parents learn from each other how to raise children with chronic conditions.

Many of these conditions are unpredictable in their implications, longevity, complications, and developmental impact on the child. The parent whose child has leukemia wonders whether new bleeding signals a relapse that will have a fatal outcome or will be followed by a permanent remission. The parent whose child has mild wheezing at bedtime does not know whether

the child will sleep well through the night or awaken severely dyspneic in the middle of the night in need of emergency care. Parents speak frequently of how difficult this unpredictability is for them and how they wish for clear answers to difficult questions, even if the answers may be unfavorable. Many important aspects of chronic disease are unpredictable, both because of great variability in environmental influences and in biologic responsiveness to specific conditions and treatments and because little information is available about many rare diseases.

Many chronic conditions and their treatments cause great *pain*, far in excess of that faced by other children. Sickle cell anemia, hemophilia, arthritis, and leukemia are examples of conditions characterized at times by severe pain.

Chronic illness has a *pervasive influence on a child's daily life*. Frequent interactions with the medical care system, occasional hospitalization, and greater dependence on parents and health care providers characterize their lives. A chronic health impairment may create a sense of “differentness,” of being unable to do many things that other children can do.

Finally, a chronic illness creates *additional stresses and demands on families and on children* that apparently healthy children do not face. Perhaps as a result, chronically ill children have about twice the frequency of psychologic or behavioral problems found in healthy control subjects; children with significant neurologic handicaps or sensory deficits have as much as a five times greater risk for these problems. The level of severity correlates poorly with psychologic status. Despite this greater risk of psychologic maladjustment, most children with chronic health conditions are psychologically healthy.

Developmental Aspects of Long-Term Illness.

Two issues are central to an understanding of the developmental implications of long-term childhood illness: the development of children's understanding of illness mechanisms and the impact of illness at different stages of child development (also see Chapters 16 and 17).

Clinicians working with children who have long-term illnesses should understand the *developmental stage of their patients' understanding of illness* in order to explain illness and its mechanisms in age-appropriate terms. Because their understanding follows a typical pattern of growth in cognitive abilities, children need different explanations of their continuing disease as they mature. Young children of preschool or early school age tend to have a concrete and relatively superficial understanding of illness. They view illness as a response to their bad behavior or not following the rules (such as wearing a coat to go outside in the cold). Children at this age believe that getting well occurs by adhering to another set of rules. By about the 4th–6th grade, children begin to differentiate themselves from external events that may cause illness. For this age group, germ theory seems very important; with the notion that germs cause almost all illnesses, illness can be prevented by avoiding germs, and better results will be gained from taking medicines, which are seen as fighting germs. This notion of germs can cause confusion or isolation for children of this age who have conditions such as leukemia or diabetes. By 8th grade or even later, children begin to understand the physiologic mechanisms for illness, appreciating the many interrelated causes and the several symptoms of illness. At this age, children usually begin to understand the interaction of body parts, for example, that lungs and hearts are not only near each other but actually work together to maintain body functions.

Physical illness has different effects on children based on their stage of development (see Chapters 7–16). In infancy, the illness may affect the parameters of growth and development by influencing feeding, sleeping, motor abilities (and therefore exploration of the environment), and sensory functions. Physical deformity or fatigue may affect a child's responsiveness to parents, who may in turn react differently to this child. Frequent hospitalizations may interfere with the normal development of trusting relationships within a family. In later preschool years, when children are developing autonomy, mobility, and self-control, illness may again interfere with

these important developmental functions. Early school-aged children may be subject to teasing from classmates; they may need to be absent from school for illness or its treatment and thus miss normal opportunities for early socialization. Middle childhood and adolescence are periods when children expand their areas of competence; responsibility for the care of the child's health condition should shift gradually from the parents to the child. Chronic illness may interfere with this process.

In adolescence, illness may affect the individual's developing independence, greater responsibility for self-care, growing intimacy, and planning for the future. The disease or its treatment may be particularly embarrassing for adolescents and may affect their body image. Adolescence is frequently a time to test the limits of the illness and compliance with recommended therapies. Health conditions that require another person for some care (such as the case of the teenager with cystic fibrosis who needs pulmonary physical therapy before each day of high school) may hinder growth toward independence. With appropriate services, most adolescents with chronic conditions make the transition to adulthood well, with little interference in their finishing education, becoming employed, and entering into significant interpersonal relationships. Sensitivity to the developmental impact of chronic illness will help clinicians provide their patients with appropriate planning and anticipatory guidance and help children and their families find acceptable ways of fulfilling the normal developmental tasks of childhood and adolescence.

Children should take increasing responsibility for the management of their own health condition commensurate with their level of maturity, developmental stage, and understanding of their illness. Areas of responsibility include monitoring the condition, assessing indicators of change and exacerbation, asking for help, and being responsible for self-medication (both at home and at school). Families may need help in learning ways to foster responsibility, and children need education and advice in learning how to become independent in appropriate ways.

Integrating Children with Chronic Conditions into Communities.

Changing interests of families, changing notions of the civil rights of people with disabilities, and improved technologies have fostered an increasing emphasis on family-centered services for children with chronic conditions. Parents increasingly take responsibility for monitoring and managing the care of their child, and more care is provided in or near the child's home and less in hospitals. Families want to receive most care in community settings and want to integrate their chronically ill child into community activities, not to limit her or him to services provided mainly for children with special health needs.

Providing services in the community also strengthens early socialization of the child, mainly through participation in child care and, later, social and educational development through participation in school programs. Chronic illness accounts for a sizable number of school absences. Part of that time away from classes reflects the direct effects of illness, such as increased fatigue or necessary hospitalization; however, some represents the need to travel great distances for treatments that are often available only during regular school hours.

Some children with chronic illnesses, especially those with cognitive impairments, need special education services. However, most children with long-term illnesses have no intrinsic cognitive impairment and should be in regular education programs. They may need specialized health services

---

(e.g., access to medicines or planning for emergencies) in order to participate in school, and children who must miss classes frequently need home or hospital instruction to allow them to keep up with their classmates.

Families whose children have long-term health conditions should have access to a wide range of coordinated and comprehensive services. The specific services needed by any one family will vary considerably from those needed by another and will change over time as the child grows and the family changes. The main groups of services that should be available for families include primary and specialized medical and surgical care; nursing services, especially those that will help to strengthen a family's own skills in caring for their child; preventive and therapeutic mental health services; social services; educational planning; and certain special therapies, such as physical therapy, occupational therapy, and nutritional services. Preventive mental health services help diminish the risk of psychologic problems related to the chronicity of the child's condition.

Partly because of the emphasis on specialized medical services and frequent surgeries, hospitalization, or other acute episodes, children with chronic health conditions may lack regular pediatric health supervision. They have lower rates of immunization and screening for common health problems and often lack anticipatory guidance in key areas of growth and development, such as behavior and discipline in the preschool years, preparation for entry to school, and preparation for adolescence, with developing sexuality, growth of independence, and opportunity for substance abuse. Lack of adequate primary care has been associated with greater likelihood of hospitalization for children with some chronic conditions such as asthma, in which preventive use of anti-inflammatory drugs can diminish the number and severity of episodes. The primary care provider should help ensure that children receive services aimed at preventing exacerbation of their condition or diminishing its severity (Chapter 5).

Pediatric Care in the Community.

Community pediatricians have a central role in the care of children with chronic illnesses and in supporting their families. Although the pediatrician's involvement may begin with diagnosis and referral to subspecialty services, he or she should also assume responsibility as a continuing advocate for the child and family. This includes continuing communication with specialty providers and helping families make informed choices, especially when advice is conflicting. Along with ongoing primary care, the pediatrician should work with subspecialty services to coordinate medical care and help with efforts to prevent morbidity. Educating parents and children about the disease process and its management, complications, and developmental implications is a central part of the therapeutic effort. Other responsibilities include continued support for children and family members, helping families locate appropriate community resources, and, especially, collaborating with schools and agencies to integrate the child into the community. Tasks with agencies include

referral to early intervention services, when appropriate; providing information that may help determine whether a child needs special or regular education services; and helping the child obtain the school services that enhance school attendance. Needed school services typically include appropriate nursing and related services and access to medications or emergency care, although a few children require more extensive services, including personal attendants.

Communication with families is particularly important. Families want clear information, with details that they can understand and information about both positive and negative aspects of the child's condition. They particularly appreciate receiving information and support from a professional familiar to them who provides compassionate and caring services. The child should also participate in developmentally appropriate ways in information sharing.

37.2 Mental Retardation

Bruce K. Shapiro
Mark L. Batshaw

Mental retardation refers to a group of disorders that have in common deficits of adaptive and intellectual function and an age of onset before maturity is reached. The designation continues to evolve as a result of new knowledge and changing societal norms.

Definition.

The most commonly used definition of mental retardation comes from the American Psychiatric Association's (APA) *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (DSM-IV-TR) (Table 37–1). This classification, although based on previous definitions, has been criticized for depending on IQ test performance rather than adaptive behavior, not taking the standard error of measurement into account, and not being predictive of outcomes for individuals.

The American Association on Mental Retardation (AAMR) has proposed a different classification. Instead of defining degrees of deficit (mild to profound), the AAMR definition substitutes levels of support required (intermittent, limited, extensive, or pervasive) in areas of adaptive function. The reliability of using the “levels of support required” has been challenged. In addition, the AAMR classification system blurs the distinction between mental retardation and other developmental disorders (e.g., communication disorder, autism, specific learning disabilities). As a result, the medical community has generally used the APA definition.

Etiology.

There appear to be two overlapping populations of retarded children: mild mental retardation, which is associated with environmental influences, and severe mental retardation, which is linked to biologic causes. Mild mental retardation is four times more likely to be found in the offspring of women who have not completed high school than in women who have graduated. This is presumably a consequence of both genetic (i.e., children may inherit a cognitive impairment) and socioeconomic (i.e., poverty, undernutrition) factors. The specific causes of mild mental retardation, however, are currently identifiable in less than half of affected individuals. The most common

TABLE 37.2-1 -- **Diagnostic Criteria for Mental Retardation**

A. Significantly subaverage intellectual functioning: an IQ score of approximately 70 or below on an individually administered clinical judgment of significantly subaverage intellectual functioning).
B. Concurrent deficits or impairments in present adaptive functioning (i.e., the person's effectiveness in meeting the her age by his or her cultural group) in at least two of the following areas: communication, self-care, home living, community resources, self-direction, functional academic skills, work, leisure, health, and safety.
C. The onset is before age 18 years.

Code based on degree of severity reflecting level of intellectual impairment:

Code	Category	Description
317	**Mild Mental Retardation:**	IQ level 50–55 to approximately 70
318.0	**Moderate Mental Retardation:**	IQ level 35–40 to 50–55
318.1	**Severe Mental Retardation:**	IQ level 20–25 to 35–40
318.2	**Profound Mental Retardation:**	IQ level below 20–25
319	**Mental Retardation, Severity Unspecified:**	when there is a strong presumption of mental retardation but the person's intelligence is untestable by standard tests

From American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision. Washington, DC, Author, 2000, p 49, reprinted by permission.

TABLE 37.2-2 -- **Identification of Cause in Children with Severe Mental Retardation**

Cause	Percent of Total
Chromosomal disorder	22
Genetic syndrome	21
Developmental brain abnormality	9
Inborn errors of metabolism/neurodegenerative disorder	8
Congenital infections	4

Familial retardation	6
Perinatal causes	4
Postnatal causes	5
Unknown	21
Total	**100**

From Stromme P, Hayberg G: Aetiology in severe and mild mental retardation: A population based study of Norwegian children.Dev Med Child Neurol 2000;42:76–86.

biologic causes of mild mental retardation include genetic syndromes with multiple minor congenital anomalies, fetal deprivation, perinatal insults, intrauterine exposure to drugs of abuse, and sex chromosomal abnormalities. Familial clustering is also frequent.

In children with severe mental retardation, a biologic cause (most commonly prenatal) can be identified in over three quarters of cases (Table 37–2). In general, the earlier the problem occurs in development, the more severe its consequences. This is consistent with finding that disorders that affect early embryogenesis are the most common and severe: These include chromosomal (e.g., Down syndrome) and other genetic syndromes (e.g., fragile X syndrome), abnormalities of brain development (e.g., lissencephaly), and inborn errors of metabolism/neurodegenerative disorders (e.g., mucopolysaccharidoses).

Epidemiology.

The prevalence of mental retardation depends on the definition used, the method of ascertainment, and the population. According to statistics (based on the APA definition), 2.5% of the population should have mental retardation, and 85% of these individuals should fall into the range of mild mental retardation. In 1997–98, approximately 600,000 children received services for mental retardation in federally supported school programs in the United States. This represented approximately 1.1% of all school-aged children. The reasons for the discrepancy between expected and observed rates of mental retardation is that fewer children than predicted are identified as having mild mental retardation. The following issues influence the identification process: (1) It is more difficult to diagnose mild mental retardation than the more severe forms. Therefore, professionals may defer the diagnosis of mental retardation and “give the benefit of the doubt” to the child. In addition, some instruments (e.g., Stanford-Binet, 4th edition) under-identify young children with mild mental retardation. Further, young children may show cognitive limitations without significant delays in adaptive behavior. As a result, new cases of mild mental retardation continue to be diagnosed until around 9 yr of age. (2) The AAMR and APA classifications of mental retardation use different definitions of significantly sub-average intellectual function. The AAMR definition increases the IQ threshold for mental retardation from 70 to 75 to reflect the standard error of IQ measurement. This definition doubles the prevalence of mental retardation. (3) Children with mental retardation may be incorporated into another diagnosis (e.g., autism, cerebral palsy). (4) It is possible that the number of children with mild mental retardation is actually decreasing as a result of public health programs.

Unlike mild mental retardation, the prevalence of severe mental retardation has not changed appreciably since the 1940s and is approximately 0.3–0.5% of the population. Many of the causes of severe mental retardation involve genetic or congenital brain malformations that can neither be anticipated nor treated at present. In addition, decreases in prevalence of severe mental retardation resulting from improved health care have been offset by new populations with severe deficits. Although prenatal diagnosis has been associated with a decreased prevalence of Down syndrome and early intervention has helped to reduce mental retardation caused by phenylketonuria and congenital hypothyroidism, the increased prevalence of prenatal exposure to drugs of abuse and the improved survival of “micro” premature infants have increased the prevalence of mental retardation.

Overall, mental retardation occurs more frequently in boys than in girls: 2:1 in mild mental retardation and 1.5:1 in severe mental retardation. This may be a consequence of X-linked disorders, the most prominent being fragile X syndrome.

Pathology/Pathogenesis.

The limitations in our knowledge of the neuropathology of mental retardation is exemplified by the fact that 10–20% of brains of individuals with severe retardation appear entirely normal by standard neuropathologic study. The majority of brains of these individuals show only mild, nonspecific changes that correlate poorly with the degree of mental retardation. These changes include microcephaly, gray matter heterotopias in the subcortical white matter, unusually regular columnar arrangement of the cortex, and neurons that are more tightly packed than usual. Only a minority of the brains show more specific changes in dendritic and synaptic organization, with dysgenesis of dendritic spines or cortical pyramidal neurons, or impaired growth of dendritic trees.

Since the early 1980s, however, the application of new molecular biologic approaches has improved our understanding of the pathogenesis of mental retardation. The programming of the

central nervous system (CNS) is now known to involve a process of induction, and CNS maturation has been defined in terms of genetic, molecular, autocrine, paracrine, and endocrine influences. In addition, several receptors, signaling molecules, and genes have been identified. Furthermore, it is now documented that the maintenance of different neuronal phenotypes in the adult brain involves the same genetic transcripts that play a crucial role during fetal development and activation of similar intracellular signal transduction. The integration of previous embryologic knowledge with this molecular information provides a clearer understanding not only of maturational changes that occur in brain development but also of how and why such changes take place. As an example of this new knowledge, a number of syndromes that were previously thought to involve complex chromosomal abnormalities have been found instead to be caused by single gene mutations involving induction. *Rubinstein-Taybi syndrome*, a disorder marked

clinically by broad thumbs and great toes, characteristic facies, and severe mental retardation, has been shown to result from a mutation in the gene encoding for the transcriptional co-activator CREB-binding protein (CBP), a factor important in the control of gene expression during early embryogenesis.

Clinical Manifestations.

Early diagnosis of mental retardation facilitates earlier intervention, realistic goal setting, easing of parental anxiety, and greater acceptance of the child in the community. Detecting, identifying, and diagnosing developmental dysfunction is a major justification for well-child care. Most children do not come to the pediatrician's attention because of “failed” screening tests but rather as a result of dysmorphisms, associated dysfunctions, or failure to meet age-appropriate expectations. There are no specific physical characteristics of mental retardation, but dysmorphisms are the earliest signs that bring children to the attention of the pediatrician. They may comprise a genetic syndrome, for example, Down syndrome, or be isolated, as in microcephaly. Associated dysfunctions are neurologic disorders that are seen more frequently in conjunction with mental retardation than in the general population, cerebral palsy and autism being examples. Most children with mental retardation, however, present because they do not keep up with their peers and fail to meet age-expected norms. In early infancy, this failure may include a lack of visual or auditory responsiveness, unusual muscle tone or posture, and feeding difficulties. Between 6 and 18 mo of age, motor delay (i.e., lack of sitting, crawling, walking) is the most common complaint. Language delay and behavior problems are common concerns after 18 mo (Table 37–3). Earlier identification of atypical development is likely to occur with more severe impairments, and mental retardation is usually identifiable by age 3 yr.

Laboratory Findings.

The most commonly used medical diagnostic testing for children with mental retardation is neuroimaging; metabolic, molecular, and chromosomal blood testing; and

TABLE 37.2-3 -- **Common Presentations of Mental Retardation by Age**

Age	Area of Concern
Newborn	Dysmorphisms
	Major organ system dysfunction (e.g., feeding and breathing)
Early infancy (2–4 mo)	Failure to interact with the environment
	Concerns about vision and hearing impairments
Later infancy (6–18 mo)	Gross motor delay
Toddlers (2–3 yr)	Language delays or difficulties
Preschool (3–5 yr)	Language difficulties or delays
	Behavior difficulties, including play
	Delays in fine motor skills: cutting, coloring, drawing
School age (over 5 yr)	Academic underachievement
	Behavior difficulties (attention, anxiety, mood, conduct, and so on)

electroencephalography (EEG). These tests should not be used, however, as screening tools for all children with mental retardation. Some children will need multiple tests and others will not require testing. Decisions on diagnostic testing should be based on the medical/family history, physical examination, testing by other disciplines, and the family's wishes. In general, karyotyping is indicated in children with multiple anomalies or positive family histories. Molecular testing for fragile X syndrome is appropriate for a male with moderate mental retardation, unusual physical features, and/or a family history of mental retardation; or a female with more subtle cognitive deficits associated with severe shyness. A child with a progressive neurologic disorder or acute behavioral changes will need metabolic investigation (e.g., urinary organic acids, plasma amino acids, blood lactate, lysosomal enzymes in lymphocytes); and a child with seizure-like episodes should have an EEG performed. Finally, children with abnormal head growth or asymmetric or new neurologic findings should have a neuroimaging procedure.

Although the aforementioned are the most common reasons for performing diagnostic tests, some children with more subtle physical or neurologic findings also can have determinable biologic causes of their mental retardation. About 6% of unexplained mental retardation can be accounted for by “micro” chromosomal abnormalities that can be identified by high resolution chromosomal banding, fluorescent *in situ* hybridization (FISH), or chromosome painting. In addition, magnetic resonance imaging scans have been found to document a significant number of subtle markers of cerebral dysgenesis in children with mental retardation. Formes frustes of amino acid and organic acid disorders have also been associated with mental retardation in addition to the more commonly associated manifestations of behavior change, lethargy, and coma.

How intensively one investigates the cause of a child's mental retardation is based on a number of factors: (1) What is the degree of mental retardation? One is less likely to find a biologic cause in a child with mild mental retardation than in a child with severe retardation. (2) Is there a specific diagnostic path to follow? If there is a medical history, a family history, or physical findings pointing to a specific disorder, a

diagnosis is more likely to be made. Conversely, in the absence of these indicators, it is difficult to choose specific tests to perform. (3) Are the parents planning on having additional children? If so, one would be more likely to intensively seek disorders for which prenatal diagnosis or a specific early treatment option is available. (4) What are the parents' wishes? Some parents have little interest in searching for the cause of the retardation and focus exclusively on treatment. Others will be so focused on obtaining a diagnosis that they will have difficulty following through on interventions until a cause has been found. Both extremes and everything in between must be respected, but supportive guidance should be provided in the context of parent education.

Diagnosis/Differential Diagnosis.

One of the roles of pediatricians is the early recognition and diagnosis of dysfunction. The developmental surveillance approach to early diagnosis of mental retardation must be multifaceted. Parental concerns and observations about their child's development should be listened to carefully because their observations have been found to be as accurate as developmental screening tests. Medical, genetic, and environmental risk factors should be recognized. Infants at high risk (e.g., history of prematurity, maternal substance abuse, perinatal insult) should be registered in newborn follow-up programs where they are evaluated periodically for developmental lags during the first 2 yr of life and referred to early intervention programs if appropriate. Developmental milestones should be recorded routinely. Abnormal appearance and function should

be assessed during health care maintenance visits. Whether developmental surveillance is a more effective technique for identification than recognition of failure to meet age-appropriate expectations (see earlier discussion) has not been established.

Before making the diagnosis of mental retardation, other disorders that affect cognitive abilities and adaptive behavior should be considered. There are conditions that mimic mental retardation and others that include mental retardation as an associated impairment; for example, over half of children with cerebral palsy (Chapter 591) or autism (Chapter 27) also have mental retardation. Differentiation of isolated cerebral palsy from mental retardation relies on motor skills being more affected than cognitive skills and on the presence of pathologic reflexes and tone changes. In autism, language and social adaptive skills are more affected than nonverbal reasoning skills whereas in mental retardation there are usually more equivalent deficits in social, motor, adaptive, and cognitive skills. Sensory deficits (severe hearing and vision loss), communication disorders, and poorly controlled seizure disorders may also mimic mental retardation, and certain progressive neurologic disorders may appear as mental retardation before regression is appreciated.

The formal diagnosis of mental retardation requires the administration of individual tests of intelligence and adaptive functioning. The most commonly used intelligence tests are the Bayley Scales of Infant Development (BSID-II), the Stanford-Binet Intelligence Scale, and the Wechsler Intelligence Scales (also see Chapter 16).

INFANT DEVELOPMENTAL TEST.

The BSID-II is used to assess language, visual problem-solving skills, behavior, fine motor skills, and gross motor skills of children between 1 month and 3½ years of age. A Mental Developmental Index (MDI) and a Psychomotor Development Index score (PDI, a measure of motor competence) are derived from the results. This test permits the differentiation of infants with severe mental retardation from typically developing infants but is less helpful in distinguishing between a typical child and one with mild mental retardation.

INTELLIGENCE TESTS IN CHILDREN.

The most commonly used psychologic tests for children older than 3 yr of age are the Wechsler Scales. The Wechsler Preschool and Primary Scale of Intelligence-revised (WPPSI-R) is used for children with mental ages of 3–7 yr. The Wechsler Intelligence Scale for Children-3rd edition (WISC-III) is used for children who function above a 6 yr mental age. Both scales contain a number of subtests in the areas of verbal and performance skills. Although children with mental retardation usually score below average on all subscale scores, they occasionally score in the average range in one or more performance areas. The Stanford-Binet Intelligence Scale is an acceptable alternative for school-aged children. It comprises 15 subtests that assess four areas of intelligence: verbal abilities, abstract/visual thinking, quantitative reasoning, and short-term memory. This permits the evaluator to determine, using some caution, areas of relative strength and weakness. The Stanford-Binet, however, tends to underidentify mental retardation in preschool-aged children.

TESTS OF ADAPTIVE FUNCTIONING.

The most commonly used test of adaptive behavior is the Vineland Adaptive Behavior Scale (VABS). This test involves parental and/or caregiver/teacher semistructured interviews that assess adaptive behavior in four domains: communication, daily living skills, socialization, and motor skills. Other tests of adaptive behavior include the Woodcock-Johnson Scales of Independent Behavior and the American Association on Mental Retardation Adaptive Behavior Scale (ABS). There is usually (but not always) a good correlation between scores on the intelligence and adaptive scales. Basic adaptive abilities (e.g., feeding, dressing, hygiene), however, are more responsive to remedial efforts than is the IQ score. Adaptive abilities are also more variable, which may relate to the underlying condition and to environmental expectations. For example, while individuals with Prader-Willi syndrome have stability of adaptive skills through adulthood, individuals with fragile X syndrome may have increasing deficits over time.

Complications.

Children with mental retardation have higher rates of vision, hearing, orthopedic, and behavioral/emotional disorders than do typically developing children. Yet, these disorders generally are detected later in children with mental retardation. If untreated, the associated impairments can potentially adversely affect the

individual's outcome more than the intellectual deficit itself.

The most common associated deficits are motor impairments, behavioral/emotional disorders, medical complications, and seizure disorders. In general, the more severe the retardation, the greater are the number and severity of associated impairments. Knowing the cause of the mental retardation can help predict which associated impairments are most likely to occur. For example, fragile X syndrome and fetal alcohol syndrome are associated with a high rate of behavioral disorders, and Down syndrome has many medical complications (e.g., hypothyroidism, atlantoaxial subluxation). If there are associated impairments, they may require ongoing physical therapy, occupational therapy, speech-language therapy, adaptive equipment, glasses, hearing aids, antiepileptic medication, and so forth. Failure to adequately identify and treat these impairments may hinder successful habilitation and result in difficulties in the school, home, and/or neighborhood environment.

Prevention.

Prevention of mental retardation can occur at many levels. Examples of primary prevention programs include (1) Heightening the public's awareness of the adverse fetal effects of alcohol and smoking; (2) Promoting maternal folic acid supplements and early prenatal care; (3) Encouraging the use of guards and railings to prevent falls and other accidents in the home; (4) Teaching about locking up medications, potential poisons, and firearms; (5) Ensuring the use of appropriate seat restraints when driving and the wearing of safety helmets when biking/skateboarding; (6) Encouraging safe sexual practices to prevent adolescent pregnancies and the transmission of sexually transmitted diseases, including HIV; and (7) Implementing immunization programs to reduce the prevalence of mental retardation due to encephalitis, meningitis, and congenital infections.

In addition, presymptomatic detection of certain disorders can result in treatment that prevents adverse consequences. State newborn screening for metabolic disorders, newborn hearing screening, and preschool lead poisoning prevention programs are examples. Radiologic screening for atlantoaxial subluxation in a child with Down syndrome is an example of presymptomatic testing in a disorder associated with mental retardation.

Treatment.

Although mental retardation is not treatable, many associated impairments are amenable to intervention and may benefit from early identification. Although most children with mental retardation do not have a behavioral or emotional disorder as an associated impairment, challenging behaviors and mental illness occur with a greater frequency in this population than among children with normal development. These disorders are the primary cause for out-of-home placements, reduced employment prospects, and decreased opportunities for social integration. Some behavioral and emotional disorders are difficult to diagnose in children with more severe mental retardation because of their limited abilities to understand, communicate, interpret, or generalize. Other disorders are masked by the

mental retardation. For example, the determination of attention-deficit/hyperactivity disorder (ADHD) in the presence of moderate to severe mental retardation is difficult, except in extreme cases. Discerning a thought disorder in someone with autism may be daunting. Finally, some behavioral conditions are unique to mental retardation: e.g., self-stimulatory, self-injurious, and stereotypical behaviors.

Although mental illness is generally of biologic origin and responds to medication, behavioral disorders may result from a mismatch between the child's abilities and the demands of the situation, organic problems, and/or family difficulties. They may also represent attempts by the child to communicate, gain attention, or avoid frustration. In assessing the challenging behavior, one must consider whether it is inappropriate for the child's mental age, rather than for his or her chronological age. When intervention is needed, an environmental change, such as a more appropriate classroom setting, may improve certain behavior problems. Behavior management techniques are also useful and psychopharmacologic agents may be appropriate in certain situations.

Medication is not useful in treating the core symptoms of mental retardation; no agent has been found to improve intellectual function. Medication may be helpful, however, in treating associated behavioral and psychiatric disorders. Psychopharmacology is generally directed at specific symptom complexes including ADHD, self-injurious behavior, aggression, anxiety, and depression. Before long-term therapy with any psychopharmacologic agent is initiated, a short trial should be conducted. Even if a medication proves successful, its use should be re-evaluated at least yearly to assess the need for continued treatment.

Supportive Care and Management.

Each child with mental retardation needs a medical home with a pediatrician who is readily accessible to the family to answer questions, help coordinate care, and discuss concerns. The role of the pediatrician includes involvement in prevention efforts, early diagnosis, identification of associated deficits, interdisciplinary management, provision of primary care, and advocacy for the child and family. The management strategies for children with mental retardation should be multi-modal, with efforts directed at all aspects of the child's life: health, education, social and recreational activities, behavior problems, and associated impairments. Support for parents and siblings should also be provided.

PRIMARY CARE.

For children with mental retardation, primary care has a number of important components: (1) Provision of the same primary care received by all other children of similar chronological age (see Chapter 5); (2) Anticipatory guidance relevant to the child's functioning: e.g., feeding, toileting, school, accident prevention, sexuality education; and (3) Assessment of issues that are specifically relevant to that child's disorder: e.g., examination of the teeth in children who exhibit bruxism, thyroid function in children with Down syndrome, vision and hearing testing in all children. The American Academy of Pediatrics has published a series of guidelines for

children with specific genetic disorders associated with mental retardation (e.g., Down, fragile X, and Williams syndrome). In addition, goals should be considered and programs adjusted as needed during the visit. Decisions should also be made about what additional information is required for future planning or to explain why the child is not meeting expectations. Other evaluations, such as formal psychologic or educational testing, may need to be scheduled.

INTERDISCIPLINARY MANAGEMENT.

The pediatrician has the responsibility for consulting with other disciplines to make the diagnosis and coordinate treatment services. Consultant services may include psychology, speech/language pathology, physical therapy, occupational therapy, audiology, nutrition, nursing, social work, as well as medical specialties such as neurology, genetics, psychiatry, and/or surgical specialties. Contact with early intervention/school personnel is equally important. The family should be an integral part of the planning and direction of this process. Care should be family centered and culturally sensitive; for the older child, his or her participation in planning and decision making should be promoted to whatever extent possible.

PERIODIC RE-EVALUATION.

The child's abilities and the family's needs change over time. As the child grows, more information must be provided to parents, goals must be reassessed, and programming needs adjusted. A periodic review should include information about the child's health status as well as his or her functioning at home, school, and in other community settings. Other information, such as formal psychologic or educational testing, may be helpful. Re-evaluation should be undertaken at routine intervals (6–12 mo during early childhood), at any time the child is not meeting expectations, or when he or she is moving from one service delivery system to another. This is especially true during the transition to adulthood, beginning at age 14 yr as mandated by the Individuals with Disabilities Education Act Amendments of 1997 (IDEA '97). This transitioning should include the transfer of care to the adult health care system by age 21.

EDUCATIONAL SERVICES.

Education is the single most important discipline involved in the treatment of children with mental retardation. The educational program must be relevant to the child's needs and address the child's individual strengths and weaknesses. The child's developmental level, his or her requirements for support, and goals for independence provide a basis for establishing an Individualized Family Support Plan (IFSP) for early intervention services or an Individualized Education Program (IEP) for school-aged children, as mandated by federal legislation.

LEISURE AND RECREATIONAL ACTIVITIES.

The child's social and recreational needs should be addressed. Although young children with mental retardation are generally included in play activities with children who have typical development, adolescents frequently do not have opportunities for appropriate social interactions and are not competitive in extracurricular sports activities. Yet, participation in sports should be encouraged because it offers many benefits, including weight management, development of physical coordination, maintenance of cardiovascular fitness, and improvement of self-image. Social activities are equally important, including dances, trips, dating, and other typical social and recreational events.

FAMILY COUNSELING.

Many families adapt well to having a child with mental retardation, but some have emotional/social difficulties. The risks of parental depression and child abuse and neglect are higher in this group of children than in the general population. Among the factors that have been associated with good family coping and parenting skills are stability of the marriage, good parental self-esteem, limited number of siblings, higher socioeconomic status, lower degree of disability/associated impairments, appropriate parental expectations and acceptance of the diagnosis, supportive extended family members, and availability of community programs and respite care services. In those families in which the emotional burden of having a child with mental retardation is great, family counseling, parent support groups, respite care, and home health services should be an integral part of the treatment plan.

ADVOCACY.

The pediatrician can play a number of advocacy roles: maintaining close contact with the department of health/local school district to advocate for an appropriate IFSP/IEP; identifying eligibility for financial supports through Supplemental Security Income (SSI) from Social Security; assessing the impact of the Americans with Disabilities Act (ADA) on the adolescent's access to jobs and community

activities; referring families to appropriate parental support groups or websites for their specific disorder/syndrome; assuring adequate respite services for the family; becoming involved in the community to help develop educational, recreational, and leisure programs for children with disabilities; and advocating for improved health care coverage by both private and governmental insurers.

Prognosis.

Mental retardation is not always a lifelong disorder. Children may meet criteria for mental retardation at an early age but later evolve into a more specific developmental disorder (e.g., communication disorder, autism, slow learner–borderline normal intelligence). Others who are diagnosed with mental retardation during their school years may develop sufficient adaptive behavior skills so that they no longer fit the diagnosis as adolescents, or the effects of maturation and plasticity may result in children moving from one diagnostic category to another (e.g., from moderate to mild retardation). Alternatively some children who are diagnosed with a specific learning disability or communication disorder may not maintain their rate of cognitive growth and fall into the range of mental retardation over time. By adolescence, however, the diagnosis has generally stabilized.

The long-term outcome of individuals with mental retardation depends on the underlying cause, the degree of cognitive and adaptive deficits, the presence of associated medical and developmental impairments, the capabilities of the families, and the school/community supports, services, and training provided to the child and family. As adults, many individuals with mild mental retardation are capable of gaining economic and social independence with functional literacy. They may need periodic supervision, however, especially when under social or economic stress. Most live successfully in the community, either independently or in supervised settings. Life expectancy is not adversely affected by mental retardation itself.

For individuals with moderate mental retardation, the goals of education are to enhance adaptive abilities and "survival" academic and vocational skills so they are better able to live in the adult world. The concept of supported employment has been very beneficial to these individuals; the person is trained by a coach to do a specific job in the setting in which the person is to work. This bypasses the need for a sheltered workshop experience and has resulted in successful work adaptation in the community for many people with mental retardation. These individuals generally live at home or in a supervised setting in the community.

As adults, people with severe-profound mental retardation usually require extensive to pervasive supports. These individuals may have associated impairments, such as cerebral palsy, behavioral disorders, epilepsy, or sensory impairments that further limit their adaptive functioning. They may perform simple tasks in supervised settings, and most people with this level of mental retardation are able to live in the community with appropriate supports.

Chapter 38 - Pediatric Palliative Care: The Care of Children with Life-Limiting Illness

Stephen Liben

In the United States more than 50,000 children die every year, resulting in over 250,000 bereaved parents, siblings, and other loved ones having their lives significantly and permanently altered. This chapter focuses on the management of unnecessary suffering of these children as well as how to better support the bereaved they leave behind.

In 1990 the World Health Organization defined palliative care as “The active total care of patients whose disease is not responsive to curative treatment. Control of pain, of other symptoms, and of psychological, social and spiritual problems, is paramount. The goal of palliative care is achievement of the best quality of life for patients and their families.” Palliative care is provided in hospitals (some with specialized palliative care units), in the home whenever possible and desired, and in hospices. Hospices provide a structured model of how to finance, maintain, and coordinate a range of palliative care services, often in a freestanding facility. In some countries specialized pediatric hospices (in contrast to adult hospices that may occasionally admit a child) provide an important bridge between hospital care and home care.

Pediatric palliative medicine is that part of palliative care that is practiced by physicians and is involved with the study and medical care of children with life-limiting (or life-threatening) illness. The mandate of pediatricians to oversee children's physical, mental, and emotional health and development from conception to maturity (Chapter 1) includes the practice of palliative medicine for those children in their care who live with a significant possibility of death before reaching adulthood. In addition, many pediatric subspecialties have a responsibility for a unique population of children at high risk for a premature death. Thus, learning the basic knowledge, attitudes, and skills of palliative medicine is integral to the education of both the generalist and subspecialist pediatrician. Such training has the added benefit of improving skills in other areas of care such as communication and symptom control.

Compared with traditional cancer-based adult end-of-life care, pediatric palliative care has:

1. Smaller numbers of dying children. This means that even professionals specializing in the care of children may only rarely encounter the death of a child. The relative infrequency of pediatric deaths has also resulted in chronic underfunding of pediatric end-of-life care services and underrepresentation of children in palliative care research protocols.
2. A broad spectrum of illnesses, including many rare diseases, that often require involvement of a number of disciplines. Although results obtained from adult oncology–based research can have benefits that apply to many palliative care patients, in pediatrics the wide range of often poorly understood disorders

limits the ability to generalize from any one disease-specific research study to another.
3. Unpredictable illness trajectories with significant prognostic uncertainty. It is often impossible to accurately predict the progression of illness for many life-threatening illnesses in pediatrics. This leads to child and family distress from uncertainty coupled with difficulty funding and sustaining pediatric palliative care programs that may need to provide varied amounts of services over years. Palliative care for these children may necessarily involve some overlap with chronic curative care, with palliative care becoming more prominent as the child progresses from being chronically to terminally ill.
4. More uncertainty about whether treatments are supportive/palliative versus those that primarily cure or prolong life. Deciding whether a specific treatment is palliative or life prolonging is not always possible with emerging technologies such as noninvasive respiratory ventilation.

Advances in pediatric medicine have resulted in an increase in the number of children who live longer, often with significant dependence on new (and expensive) technologies. These children have complex chronic conditions across the spectrum of congenital and acquired life-threatening disorders (Chapter 37). Children with complex chronic conditions require a combination of palliative and curative treatments. These children, who may survive frequent near-death crises followed by the renewed need for rehabilitative and life-prolonging treatments, are best served by a system that is flexible and responsive to changing needs.

Care Planning.

Although it may not be possible to accurately determine how long a child may live, there is often a delay between the time when a terminal prognosis is first recognized by physicians and when the prognosis is understood by parents. This time delay may impede informed decision-making about how these children spend the end of their lives. Given the inherent prognostic uncertainty of a life-limiting diagnosis, the time when the physician recognizes a significant possibility of patient mortality is probably the best time to initiate discussions concerning resuscitation, symptom control, and end-of-life care planning. Patients and families may be most comfortable continuing with physicians and other care providers with whom they have an established relationship; in most cases the services of a palliative care specialist or *hospice program* can be consultative to the primary or subspecialty care physician and team.

Physician discomfort in discussing end-of-life care should not result in the discussion being deferred to others or to a later time. Physician feelings of discomfort are to be expected given the difficult nature and highly charged atmosphere of a child facing death, and physicians may need varying levels of support themselves as they map out a care plan with the child and parents. At times, for a variety of reasons including limited local resources and experience or the need for concurrent respite and care of other family members, transfer to a hospital, or home care, or hospice palliative care program may be necessary.

Home care of the dying child requires 24?hr per day accessibility to experts in pediatric palliative care, a team approach, and an identified coordinator who serves as a link between hospitals, the community, and specialists, and can arrange for hospital admissions and respite care, as needed. Provision of *respite services* is especially important to families caring for children with complex chronic conditions over prolonged periods of time. Such care may involve temporary placement of a child with another family or in an institution such as a hospital or hospice. It is important to plan a respite admission before the family caring for the child feels overwhelmed. The family should be reassured that taking respite is not a personal failure. Although children, when given the choice, prefer to remain at home, a child may need to periodically return to the hospital or hospice even when there is comprehensive home support.

Good end-of-life care can be effectively carried out in a *hospital setting* but only when institutions are flexible enough to modify protocols that may present unnecessary obstacles to the care of dying patients. Within tertiary care hospitals the neonatal and pediatric intensive care units (ICUs) are the locations where most children die (Chapter 64). Many of the children in ICUs die after discussions that lead to the limitation or withdrawal of therapy. Improving the care of these hospitalized children and their families involves liberalizing visiting policies and respecting privacy, as well as removing some of the obstacles inherent in intensive care settings, such as routine testing and monitoring of vital signs. The philosophy of palliative care can be successfully implemented in a hospital setting when the focus of care is maintained on comfort and quality of life. All interventions that affect the child and family need to be assessed in relation to these goals. This proactive approach asks the question “What can we offer that will improve the quality of this child's life?” instead of “What therapies are we no longer going to offer this patient?” Staff who are comfortable and supportive of this approach need to be carefully chosen with consideration given to the fact that pediatric palliative care, like other types of intensive care, is not a skill with which everyone is comfortable. In addition, comprehensive palliative care requires a multidisciplinary approach that may include nurses, physicians, psychologists, psychiatrists, social workers, religious counselors, child-life specialists, and trained volunteers.

Communication Issues and Anticipatory Guidance

THE CHILD.

Responding to children's questions about death, such as “What's happening to me? Am I dying?”, requires a careful exploration of what is already known by the child, what is really being asked (the question behind the question), and why the question is being asked at this particular time and in this setting. A child's perception of death depends on his or her concepts of universality (the recognition that all things inevitably die), irreversibility (the ability to understand that dead people cannot come back to life), nonfunctionality (the understanding that being dead means that all biologic functions cease), and causality (the ability to understand the objective causes of death). See Chapter 33 . Children's fears of death are centered on the concrete fear of being separated from parents and other loved ones, rather than on the existential consequences of an afterlife common to adults. This fear of separation may be responded to in different ways, with some families giving reassurance that loving relatives will be waiting, and others using religious figures or referring to an eternal spiritual connection (“I will always be there for you”). Adolescents have their own unique issues, including risk-taking behavior that seems to challenge their concept of universality (“I am invincible”).

It is also important to recognize that a child's expressed question may have different levels of meaning. A child asking, “Am I dying?” may really be testing the honesty of the person being asked. The child asking, “Why is this happening to me?” may be signaling a need to be with someone who is comfortable listening to such unanswerable questions. Many children find nonverbal expression much easier than talking; art, play therapy, and storytelling may be more helpful than direct conversation. Parents have an instinctive duty to protect their children from harm. When facing the death of their child many parents attempt to keep the reality of impending death hidden from their children with the hope that their child can be “protected” from the harsh reality. Although it is important to respect parental wishes to avoid the subject of death with their children, it is also true that many young children already know what is happening to them even when it has been purposely left unspoken. Perpetuating the

myth that “everything is going to be all right” takes away the chance to explore fears and provide reassurance. For example, children may blame themselves for their illness and the hardships that it causes for their loved ones. Their guilt can be addressed and resolved only by open, honest communication, requiring a sensitive response that takes into account the child's developmental stage and unique lived experience.

THE SIBLINGS.

Brothers and sisters are at special risk both during the course of their sibling's illness and after their death. Because of the extraordinary demands placed on parents to meet the needs of their ill child, healthy siblings may feel that their own needs are not being acknowledged. These feelings of neglect may then trigger guilt about their own good health and resentment towards parents and their ill sibling. Younger siblings may react to the stress by becoming seemingly oblivious to the turmoil around them. Parents need to know that this is a normal response, and siblings should be encouraged to maintain the normal routines of daily living. Siblings who are most involved with their sick brothers or sisters before death usually adjust better both at the time of and after the death. Acknowledging and validating sibling feelings, being honest and open, and appropriately involving them in the life of their sick sibling provide a good foundation for coping with loss.

THE PARENTS.

The populations of children who die before reaching adulthood include a disproportionate number of nonverbal and preverbal children who are developmentally unable to make autonomous care decisions. For these children it is parents that take on the role of primary decision-maker. Parents may blame themselves for their child's illness even when logic dictates that they had nothing to do with what is happening to their child (“If only I had taken him to the doctor sooner”) and may spend considerable energy and resources looking for “miracle cures.” The physician should be sensitive to these possible and not necessarily easily expressed parental concerns. There is potential for physicians to provide much needed support to parents at these times by engaging in active listening while validating the range of concerns that parents may have. Parents also need to know about the availability of home care, respite services, educational books and videotapes, and support groups. It is important to discuss how parents envision their child's death and to address myths surrounding pain control and the benefit of involving siblings. What all parents want to know is that their physician will not abandon them as the goals of care shift primarily from cure to comfort. Physicians should recognize the important role they have in continuing to care for the child and family as the primary goal of treatment changes from prolongation of life to quality of life. Regular meetings between caregivers and the family are essential in order to reassess and manage symptoms, explore the impact of illness on immediate family members, and provide anticipatory guidance. At these meetings, important issues include finding an appropriate physical setting for the meeting (i.e., not a hospital corridor), reviewing what was previously discussed, listening to concerns and issues as they are revealed, having parents repeat back what was said to ensure clarity, and responding with honest, factual answers in areas of uncertainty.

In communications with the child and family, the physician should avoid giving estimates of survival length, even when these are explicitly asked for. These predictions are invariably inaccurate because population-based statistics do not predict the course for individual patients. A more honest approach may be to explore ranges of time in general terms (“weeks to months,” “months to years”). At the same time, the physician can ask parents what they might do differently if they knew how long their child would live and then assist them in thinking through the options relating to their specific concerns (e.g., suggest celebrating upcoming holidays/important events earlier in order to take advantage of times when the child may be feeling better). It is generally wise to suggest that relatives who wish to visit might do so earlier rather than later given the unpredictability of the time course of many illnesses. For the child and family the integration of bad news is a process, not an event. The physician should expect that some issues previously discussed may not be fully resolved for the child and parents (e.g., do not resuscitate orders, artificial feedings) and may need to be revisited over time.

Decision-Making.

During the course of a child's life-limiting illness, a series of difficult decisions need to be made in relation to truth telling and disclosure, location of care, medications with risks and benefits (e.g., steroids), the principle of double effect in the beneficent use of analgesics, withholding and or withdrawing life-prolonging technologies, experimental treatments in research protocols, and the use of “alternative” therapies (also see Chapters 2 and 3). Decision-making should remain focused on the goals of therapy rather than on specific limitations of care; e.g., “This is what we can offer,” instead of “This is what we can no longer do.” Instead of meeting specifically to discuss a do-not-resuscitate order, a more general discussion centered on the goals of therapy will naturally lead to considering which interventions are in the child's best interests. Unclear terms used in doctor's orders in the chart such as “withholding heroic or extraordinary measures” are best replaced by reference to specific interventions that are then documented in a care plan (e.g., “suction airway secretions prn” rather than “do not do lab tests”). It is important to support parents in their decision-making process rather than to make them feel that it is up to them alone to choose what is best. Rather than asking parents if they want to forgo cardiopulmonary resuscitation for their child (placing the full burden of decision-making on them), it might be preferable to discuss why deciding against resuscitation attempts is a reasonable course of action. Once the goals of therapy are agreed upon, the physician may draft a letter that outlines the end-of-life care plan for the child. The letter should be as detailed as possible, including suggestions for medications and the telephone numbers of caregivers who know the patient best. Such a letter, given to the parents, with copies to involved caregivers and institutions, can be a useful aid in communication, especially in times of crisis.

Conflicts in decision-making (see Chapters 2 and 54) can occur within families, within health care teams, between the child and family, and between the family and professional caregivers. For children who are developmentally unable to provide guidance in decision-making (neonates, very young children, neurologically impaired children) parents and health care professionals may come to different conclusions as to what is in the child's best interests. In some families and cultures truth telling and autonomy are much less valued when compared with family integrity (Chapter 3). Although frequently encountered, differences in opinion are often manageable for all involved when lines of communication are kept open and the main goals of care, to provide comfort and quality of life, are agreed upon. Decision-making with adolescents presents specific challenges given the shifting boundary that separates childhood from adulthood (Chapters 2 , 14 , and 100).

Euthanasia is the intentional, active intervention to terminate a life. The withdrawal of treatments with burdens that outweigh benefits is not euthanasia (Chapters 2 and 64). Providing sufficient analgesia to relieve pain, even if it may have the unintentional effect of shortening life (the principle of double effect), is not the same as intentionally terminating a life. Although controversial, most palliative care professionals would argue against euthanasia and physician-assisted suicide (physicians explicitly providing the means to cause death) because it is unlikely that children or adolescents will actively seek death when they are receiving appropriate pain relief and palliative care.

Symptom Management.

Pain control is of paramount importance in reducing the suffering of the child, family, and caregivers, but many dying children do not have their pain successfully treated. See Chapters 66 , 87 , and 486 for effective management of pain. In 1998 the World Health Organization stated: “Nothing would have a greater impact on the quality of

life of children with cancer than the dissemination and implementation of the current principles of palliative care, including pain relief and symptom control.”

Pain is a complex sensation influenced by tissue damage as well as by situational factors, including cognitive, behavioral, emotional, social, and cultural issues that are unique to each person. In end-of-life care it is important to form and initiate a pain treatment plan even when the diagnosis may be unclear, the prognosis uncertain, and the ability of the child to communicate limited. Many children with life-limiting illness are unable to verbalize their symptoms and will instead communicate their discomfort nonverbally. Presumptive therapy should be initiated promptly, and treatment plans can then be modified based on the response. For the dying child, in whom accurate assessment of the cause of pain may be difficult, it is important to frequently reassess therapy and to honestly inform parents that it may take several dose and medication adjustments in order to determine optimal analgesic requirements. Guidelines for the treatment of pain and the use of opioids are summarized in Tables 38–1 and 38–2 .

Dying children have a multitude of symptoms, in addition to pain, for significant periods before their death. Respiratory symptoms such as *dyspnea* (the subjective sensation of shortness of breath) are common because many children with chronic illnesses have difficulty swallowing and handling their airway secretions. Excessive airway secretions and salivation owing to poor swallowing may sometimes be helped by treatment with oral glycopyrrolate. As death approaches, a buildup of secretions may result in noisy respiration sometimes referred to as a death rattle. Patients at this stage are usually unconscious, and noisy respirations are often more distressing for others than for the child. Pointing out to parents the child's lack of distress and using an anticholinergic drug, such as hyoscine, may be helpful. Pneumonia is a frequent complication in dying children. Dyspnea (as opposed to tachypnea which may not be associated with feelings of distress) can be relieved with the use of regularly scheduled plus as-needed doses of opioids. Oxygen may be helpful in certain cases to relieve hypoxemia-related headaches. As with all medical interventions the question must be asked, “Who is being treated—the child, parents, or staff?” For example, giving oxygen to the cyanotic child who is otherwise quiet and relaxed may serve to relieve only staff discomfort while having no impact on patient distress.

Neurologic symptoms include *seizures* that are often part of the antecedent illness but may increase in frequency and severity toward the end of life. Anticonvulsants should be administered, and parents can be taught to use rectal diazepam at home. Increased *irritability* accompanies some neurodegenerative disorders;

TABLE 38-1 -- **Pain and Symptom Management**

Establish realistic goals of treatment—maintaining comfort is a priority.
Anticipate and plan for symptoms before they occur.
Utilize a stepwise approach to pain management (see Figure 66–1).
Choose the least invasive route for medications—by mouth whenever possible.
Prescribe regular (not PRN) medications for constant pain.
Consider use of adjuvant drugs:
• Antidepressants and anticonvulsants—neuropathic pain • Neuroleptics—nausea, agitation • Sedatives and hypnotics—anxiety or muscle spasm • Steroids—resistant pain • Stimulants—opioid-induced somnolence
Consider anesthetic blocks for regional pain. Use topical local anesthetics when possible (see Chapter 66).
Always include cognitive (guided imagery, distraction), physical (TENS, physiotherapy, massage), and behavioral (biofeedback, behavior modification) techniques.
TENS = transcutaneous electrical nerve stimulation.

it may be particularly disruptive because of the resultant break in normal sleep-wake patterns and the difficulty in finding respite facilities for children who have prolonged crying. Judicious use of sedatives in the daytime (e.g., benzodiazepines) combined with hypnotics at night (e.g., chloral hydrate) may achieve a balance that can dramatically improve the quality of life for both child and caregivers.

Feeding and *hydration* issues raise ethical questions that include the use of nasogastric and gastrostomy feedings for the child who can no longer feed by mouth (see also Chapter 2). These complex questions require evaluating the risks and benefits of artificial feedings and taking into consideration the child's functional level and prognosis. At times it may be appropriate to initiate a trial of tube feedings with the understanding that they may be discontinued at a later stage of the illness. A commonly held but unsubstantiated belief is that hydration is a “comfort measure,” which may result in well-meaning but disruptive and invasive attempts to administer intravenous fluids to a dying child. Studies of dying adults show that the sensation of thirst may be alleviated by careful efforts to keep the mouth moist and clean. There may also be deleterious side effects to artificial hydration in the form of increased secretions, need for frequent urination, and exacerbation of dyspnea.

Nausea demands prompt treatment after a search for common causes (drug effects, constipation, primary disease, metabolic disturbance). Drugs such as metoclopramide, phenothiazines, ondansetron, and steroids may be used depending on the cause and desired secondary effects (e.g., if sedation is desired, a sedating phenothiazine may be used). *Vomiting* may accompany nausea but may also occur

without nausea in the presence of bowel obstruction. *Constipation* is common in neurologic disorders, and the first step is to assess stool frequency and quantity. Children with minimal solid food intake may be comfortable with bowel movements as infrequent as weekly. Children on

TABLE 38-2 -- **Opioid Use Guidelines**

Clarify the differences between tolerance vs. physical dependence vs. addiction.
Dispel the myth that strong medications should be saved for last.
Anticipate and treat/prevent common side effects (constipation, pruritus, nausea, dysphoria, somnolence).
Always start constipation treatment when starting opioids.
Begin with weak opioids for mild pain (e.g., codeine). Replace with strong opioids (e.g., morphine) for unresponsive or persisting pain (see Figure 66–1).
Start with short-acting opioids at regular intervals then convert to long-acting only when dose requirements have stabilized.
Consider switching to a different opioid when limited by side effects (e.g., myoclonus).
Consider subcutaneous infusions when oral/rectal routes are no longer possible.

regular opioids should routinely be placed on stool softeners (docusate) and may also need the addition of laxative agents (senna derivatives, lactulose). *Diarrhea* may be particularly difficult for the child and family and may be treated with loperamide and opioids. Paradoxical diarrhea, a result of overflow resulting from constipation, must also be considered.

Hematologic issues include consideration of transfusions for anemia and thrombocytopenia. Most children in the palliative phase may be managed by intermittent red cell and platelet transfusions for bleeding that interferes with the quality of life. Serious bleeding is disturbing for all concerned, and a plan involving the use of fast-acting sedatives should be prepared in advance.

Skin care issues include the prevention of problems such as bedsores by the early use of inexpensive egg-crate type foam mattresses and careful attention to positioning. Pruritus may be secondary to systemic disorders or drug therapy. Treatment includes avoiding excessive use of soap, using moisturizers, trimming fingernails, and wearing loose-fitting clothing, in addition to administering topical or systemic steroids. Oral antihistamines and other specific therapies may also be indicated (e.g., cholestyramine in biliary disease).

When discussing possible therapies or interventions with adolescent patients or with the parents of any ill child, it is important to raise the issue of complementary or alternative medicine because it has been shown that many patients use some form of alternative medicine therapy but are reluctant to bring it up with their physician (Chapters 3 and 713). Although mostly unproven, some therapies are inexpensive and provide relief to individual patients. Other therapies may be expensive, painful, intrusive, and even dangerous. By initiating conversation and inviting discussion in a nonjudgmental way, the physician can offer advice on the safety of different therapies and may help avoid expensive and dangerous interventions.

The Terminal Phase.

As death approaches, the major tasks of the physician are to help prepare the child and family for expected problems and issues and to continue to stay involved in care. If the child is at home, regular phone calls should be made to help manage new symptoms as they occur (e.g., terminal airway secretions, seizures, irritability, myoclonus, vomiting). Legal issues such as who will perform the declaration of death may be addressed, and the necessary documents can be partially filled out and left in a sealed envelope in the child's home. For children in the hospital, the care plan should be clear to all involved professionals and should include an understanding of the specific needs and requests of the child and family.

Initiating a discussion of the options for funeral arrangements may be appropriate inasmuch as some parents prefer to settle these practical issues before the child's death. Attendance of young siblings at the funeral should be discussed and sibling participation encouraged. Excluding siblings from the funeral deprives them of an opportunity for partial closure and may devalue their need to grieve.

In an intensive care setting, where technology can put distance between the child and parent, the physician should discontinue the use of unneeded equipment. While still in the ICU, even children on ventilators can be placed in their parents' arms. Parents who may not have held their infant since birth may be afraid to ask permission to hold their child but will be relieved to be offered the opportunity when it is presented. Hearing and the ability to sense touch is often present until death. Siblings and family members should be encouraged to talk to and touch the child, even if he or she seems unresponsive. It seems that many children who live with prolonged illness die only after their parents have begun the process of “letting go.” Some children appear to wait for “permission to die,” and their parents' acceptance of the inevitable may play a role in the timing of their death.

For the family, the moment of death is an event that is recalled in detail for years to come. After death, they should be given the option of remaining with their child for as long as they would like. During this time, physicians and other professionals do best by not trying to “do and say too much.” Quietly sitting with the family and asking whether they would consider holding the infant may be appropriate in some cultures. Different ethnic and cultural practices should be taken into consideration and facilitated (Chapter 3). In some traditions it is important to have the family take the child to the place of worship directly instead of passing through the hospital morgue. Arranging this and other details in advance will help avoid some stress for both family and staff.

The physician should discuss the option of an autopsy and organ donation, answering questions that parents may be reluctant to ask (e.g., Will the face be disturbed?). Parents might also be reminded that they may have questions later on that can be answered by an autopsy (e.g., “Will present and future siblings and grandchildren be affected?”). The parents can also be offered genetic counseling

when appropriate.

The physician's decision to attend the funeral is a personal one. It may serve the dual purpose of showing respect as well as helping him or her cope with a personal sense of loss.

Bereavement involves a complex, individualized process that is only partially understood. What is known is that the death of a child is not something to “get over,” and intense feelings of sadness may persist for years. The physician should arrange to meet with the family at a set time after the death, to review autopsy results if applicable, and to answer questions that may remain. When the death occurs after a prolonged hospitalization, a hospital memorial service may be held. These services often serve as an opportunity for closure by staff who were involved in care but who may not have been present at the child's death.

The physician can be proactive in preventing the phenomenon of replacement children. Physicians have in the past suggested to parents, “Get on with your lives,” and “Why not have another child as soon as possible?” Instead, parents should be made aware that nothing can replace the uniqueness of their deceased child and that, although their memories will remain forever, the pain for most does subside with time. Physicians should also be aware that the divorce rate for bereaved couples is not necessarily higher than for the general population. Divorce is, therefore, not an inevitable result of the grieving process and couples should be referred for counseling when appropriate.

Because grieving for a deceased child is among the most stressful of life experiences, it is recommended that a professional trained in bereavement counseling be consulted following the death of a child. Long-term follow-up should be the norm, including regular phone calls at significant times such as birthdays, anniversaries of the death, and significant holidays. Other interventions that may be helpful include support groups for bereaved parents and siblings, where those who share common experiences can learn from one another. Such support groups include The Compassionate Friends and Candlelighters/ Lamplighters.

The Pediatrician.

Care for children with life-limiting illness places unique and at times intense demands on the pediatrician. The ability to care effectively for dying children and their families is not a skill shared by all. Most pediatricians have had little, if any, formal palliative care education and limited

clinical experience in how to care for a dying child. In addition, there are situations and times in the professional's own life when the demands of end-of-life care for their patients may be especially difficult (e.g., at times of the physician's own personal losses). At such times the availability of supportive colleagues is invaluable, and it may be appropriate and in the patient's best interest to refer to others. However, for most physicians, the duty to care for their patients through the illness spectrum including the terminal phase is a commitment that reaches to the core of their professional identity. Most physicians have had training that emphasized their role as conquerors of disease. This notion, coupled with limited training in psychosocial care, in communication skills, and in pain and symptom management may promote a feeling of personal and professional failure when facing the death of a patient. Like many aspects of medical practice, palliative medicine requires that physicians evolve their own knowledge, skills, and attitudes about healing and their unique role in caring even when death is the unavoidable outcome for their patients. Pediatricians caring for dying children and their families may require supervision from other trained professionals in examining their personal feelings, values, and attitudes about the meaning and goals of their work.

Chapter 39 - Children at Special Risk

Richard E. Behrman

In this chapter, the health issues faced by some of the most socioculturally and economically disadvantaged children in the United States are discussed: Native Americans, migrants, immigrants, homeless children, and runaways. Children in foster care are discussed in Chapter 31 . The role of poverty in the lives of these and other children has a special significance. The biologic causes of special risk are covered elsewhere. The nonbiologic and biologic causes of special risk often overlap and may confound the risks.

Most children in the United States today grow up loved and supported, although many have problems that disturb their parents and blight their future. However, for a small but significant number of children, their circumstances are so dismal that one wonders how they survive with hope for any quality of future life. Examples of children with even more dismal futures than these also exist elsewhere in the world, such as children growing up in the midst of the Israel-Palestine conflict or in Northern Ireland, Bosnia, Rwanda, or Afghanistan. Many of the children growing up in these environments will be damaged and their futures will be compromised, unless effective interventions are mounted. However, in all of these situations, a few children are so resilient that they survive and actually thrive. Werner has characterized these children as "vulnerable but invincible." The fact that a few defy the odds does not absolve society from attempting to help the majority of those who do not, although these resilient ones can teach us what it takes to survive.

The majority of children at special risk need a nurturing environment but have had their futures compromised by actions or policies arising from their families, schools, communities, and nation. The challenge is to improve the environment of these children so that most can achieve their full potential. Many of their problems are due to several causes, and many of these causes are similar, whether the end result is homeless children, runaways, children in foster care, or other disadvantaged groups. From a preventive point of view, the most effective approach involves alleviation of poverty, poor housing, and lack of jobs. From a treatment point of view, optimal care of these children requires specially organized programs, multidiscipline teams, and special financing.

CHILDREN IN POVERTY

Poverty and economic loss diminish the capacity of parents to be supportive, consistent, and involved with their children. Clinicians need to be especially alert to the development and behavior of children whose parents have lost their jobs or who live in permanent poverty. Fathers who become unemployed frequently develop psychosomatic symptoms, and their children often develop similar symptoms. Young children who grew up in the Great Depression and whose parents were subject to acute poverty suffered more than older children, especially if the older ones were able to take on responsibilities for helping the family economically. Such responsibilities during adolescence seem to give purpose and direction to an adolescent's life. But the younger children, faced with parental depression and unable to do anything to help, suffered a higher frequency of illness and a diminished capacity to lead productive lives even as adults. Children who are poor have higher than average rates of death and illness from almost all causes (exceptions being suicide and motor vehicle accidents, which are most common among white, nonpoor children) (Table 39–1). Also see Chapter 1 .

TABLE 39-1 -- **Relative Frequency of Health Problems in Low-Income Children Compared with Other Children**

Health Problem	Relative Frequency in Low-Income Children
Low birthweight	Double
Delayed immunization	Triple
Asthma	Higher
Bacterial meningitis	Double
Rheumatic fever	Double to triple
Lead poisoning	Triple
Neonatal death	1.5 times
Postneonatal death	Double to triple
Child deaths due to accidents	Double to triple
Child deaths due to disease	Triple to quadruple
Complications of appendicitis	Double to triple
Diabetic ketoacidosis	Double
Complications of bacterial meningitis	Double to triple

Per cent with conditions limiting school activity	Double to triple
Lost school days	40% more
Severely impaired vision	Double to triple
Severe iron-deficiency anemia	Double

From Starfield B: Effectiveness of Medical Care: Validating Clinical Wisdom. *Baltimore, Johns Hopkins University Press, 1985. In Starfield B: Child and adolescent health status measures.* Future Child *1992;2:25.*

Although physicians cannot cure poverty, they have a responsibility to ask parents about their economic resources, adverse changes in their financial situation, and the family's attempts to cope. Encouraging concrete methods of coping, suggesting ways to reduce stressful social circumstances while increasing social networks that are supportive, and referring patients and their families to appropriate welfare, job training, and family agencies can significantly improve the health and functioning of children at risk when their families live in poverty. In many cases, special services, especially social services, need to be added to the traditional medical services, and outreach is required to find and encourage parents to use health services and bring their children into the health care system.

Poverty among children in the United States was 16.2% in 2000, a rate among the highest of developed countries. The rates are higher for children than adults and are highest for infants and toddlers. The rates also vary substantially among ethnic groups (Chapter 1). Many factors associated with poverty are responsible for the illnesses seen in these children—crowding, poor hygiene and health care, poor diet, environmental pollution, poor education, and stress.

NATIVE AMERICANS, INCLUDING ALASKAN ESKIMOS AND ALEUTS

Children of Native Americans have higher than average rates of many physical and psychologic disorders. They are one group in the United States for whom a separately organized health service has long been in place, the Indian Health Service. There are approximately 2.5 million Native Americans, with a much higher proportion of children than for the remainder of the U.S. population. More than 50% of Native Americans live in urban areas, not on or near native lands. The unemployment and poverty levels of Native Americans are, respectively, three- and fourfold that of the white population and far fewer Native Americans graduate from high school or go on to college.

The rate of low birthweight is more than the white rate and less than the black rate. The neonatal mortality rate and the postneonatal mortality rate are higher for Native Americans living in urban areas than for urban white Americans. Deaths during the 1st yr of life due to sudden infant death syndrome and pneumonia and influenza are higher than the average in the United States, whereas deaths due to congenital anomalies, respiratory distress syndrome, and disorders relating to short gestation and low birthweight are similar.

Accidental death among Native Americans occurs at twice the rate for other U.S. populations, whereas deaths due to malignant neoplasms are lower. During adolescence and young adulthood, suicide and homicide are the second and third causes of death in this population and occur at about twice the rates of the rest of the population. There may be significant underreporting of deaths of Native American children.

Recurrent otitis media is an especially frequent problem among Native American children. As many as three quarters of these children have recurrent otitis media and high rates of hearing loss. This results in learning problems for many children. Other infectious disorders, such as tuberculosis and gastroenteritis, which were so much more common among Native Americans in the past, now occur at about the national average. The asthma-related hospitalization patterns of Native American children are similar to those in white children despite having socioeconomic characteristics more similar to those of black children.

Psychosocial problems are more prevalent in these populations than in the general population: depression, alcoholism, drug abuse, out-of-wedlock teenage pregnancy, school failure and dropout, and child abuse and neglect. The reasons for these differences are not clear, but the cultural disruption of Native American populations is probably, in part, responsible.

Indian Health Service.

Since 1954, the Indian Health Service has been the responsibility of the Public Health Service but the 1975 Indian Self-Determination Act gave tribes the option of managing Native American health services in their communities. Thus, today, the Indian Health Service is managed through local administrative units, and some tribes contract outside of the Indian Health Service for health care. A great deal of the emphasis is on adult services: treatment for alcoholism, nutrition and dietetic counseling, and public health nursing services. In addition to programs on Native American reservations, there are currently more than 40 urban programs for Native Americans, with an emphasis on increasing access of this population to existing health services, providing special social services, and developing self-help groups. In an effort to accommodate traditional Western medical, psychologic, and social services to the Native American cultures, such programs increasingly include the “Talking Circle,” the “Sweat Lodge,” and other interventions based on Native American culture (see Chapter 3). The efficacy of any of these programs, especially those to prevent and treat the sociopsychologic problems particular to Native Americans, has not been assessed.

CHILDREN OF MIGRANT FARM WORKERS

There are estimated to be 3–5 million migrant and seasonal farm workers and their families in the United States. The eastern stream of workers winters primarily in Florida, whereas the western stream comes from Texas and the border states, as well as from Mexico. Many children travel with their parents in the migrant streams. The circumstances of migrants often include poor housing, frequent moves, and a socioeconomic system controlled by a crew boss who arranges the jobs, provides transportation, and often, together with the farm owners, provides food, alcohol, and drugs under a "company store" system that leaves migrant families with little money or even in debt at the end of the year. Children often go without schooling because of the moves, and medical care is usually limited.

The medical problems of children of migrant farm workers are similar to those of children of homeless families: increased frequency of infections (including human immunodeficiency virus [HIV] and AIDS), trauma, poor nutrition, poor dental care, low immunization rates, exposures to toxic chemicals, anemia, and developmental delays.

In 1964, the Public Health Service initiated a special program to provide funds for local groups to organize medical care for migrant families. This program has continued to grow. In addition, many migrant health projects, which were staffed initially by part-time providers and were open for only part of the year, have been transformed into community health care centers that provide services not only for migrants but also for other residents in the area. However, health services for migrant farm workers often need to be organized separately from existing primary care programs because the families are migratory. Special record-keeping systems that link the health care provided during winter months in the south with the care provided during the migratory season in the north are difficult to maintain in ordinary group practices or individual physicians' offices. Outreach programs that take medical care to the often remote farm sites are necessary, and specially organized Head Start, early education, and remedial education programs should also be provided. Similar to other groups discussed in this section, children of migrant farm workers require health care that is more extensive than physicians' services, and this

sort of health care often requires separate organizations to deliver it.

CHILDREN OF IMMIGRANTS

The United States has always been a country of immigrants, and it is in the midst of a wave of immigration larger than that experienced in the early 1900s. There has been a marked increase in immigration from Southeast Asia, South America, and the Soviet Union. About 240,000 children legally immigrate each year, and an estimated 50,000/yr enter the country illegally. During the past decade, about 9 million immigrants attained permanent residency status. There may be 850,000 to 1 million illegal immigrant children currently in residence. Families of different origins obviously bring different health problems and different cultural backgrounds, which influence health practices and use of medical care and need to be understood to provide appropriate services (see Chapter 3). Children from Southeast Asia and South America have growth patterns that are generally below the norms established for children of Western European origin, and high rates of hepatitis, parasitic diseases, and nutritional deficiencies are prevalent, as well as high degrees of psychosocial stress. The high prevalence of hepatitis among women from Southeast Asia makes use of hepatitis B vaccine essential for newborns in this group.

Refugee children who escape from war or political violence and whose families have been subjected to extreme stress are a subset of immigrant children. They have a particularly high incidence of mental and behavioral problems. Also see Chapter 22 for discussion of traumatic stress disorder.

Although special health care programs have been developed for many of these children (e.g., children of immigrant migrant workers), children of legal immigrant families have usually been more readily incorporated into traditional medical practice in the United States than some of the other groups of children at special risk. However, "linguistically isolated households," in which no one older than 14 yr of age speaks English, often present significant obstacles to providing quality health care to children because of difficulties in understanding and communicating basic concerns and instructions and in avoiding compromising privacy and confidentiality interests and obtaining informed consent when using translators.

HOMELESS CHILDREN

Families with children are the fastest growing segment of the homeless population (about 40%). Children make up about 25% of the homeless population, with an estimated 100,000 children living in shelters on a given night and about 500,000 homeless each year. Many homeless are not in shelters, and thus, these figures are low estimates. In addition, an unknown number of thrown-away and runaway children and adolescents are homeless, living in shelters, on the streets, and elsewhere (see later). The population of homeless children has been increasing as a consequence of more families with children living in poverty or near poverty, fewer available affordable dwellings for these families, decreasing public assistance programs for the non-elderly poor, and the rising prevalence of substance abuse.

Homeless children have an increased frequency of illness, including intestinal infections, anemia, neurologic disorders, seizures, behavioral disorders, mental illness, and dental problems, as well as increased frequency of trauma and substance abuse. Homeless children are admitted to hospitals at a much higher rate than the national average. They have higher school failure rates, and the likelihood of their being victims of abuse and neglect is much higher. In one study, 50% of such children were found to have psychosocial problems, such as developmental delays, severe depression, or learning disorders. The increased frequency of maternal psychosocial problems, especially depression, in homeless households has a significant untoward impact on the mental and physical health of these children.

Because families tend to break apart under the strain of poverty and homelessness, many homeless children end up in foster care. And even if their families remain intact, frequent moves make it very difficult for them to receive continuity of medical care. Homeless persons rarely have a family physician, and therefore special programs generally need to be developed to provide health services for this

population. Mobile vans, with a team consisting of a physician, nurse, social worker, and welfare worker, have been shown to provide effective comprehensive care, ensure delivery of immunizations, link the children to school health services, and bring the children and their families into a stable relation with the traditional medical system. A special record-keeping system is necessary to enhance continuity and to provide a record of care once the family has moved to a permanent location. Because of the high frequency of developmental delays in this group, linkage of preschool homeless children to Head Start programs is an especially important service. Medical and social services for the parents of homeless children are also essential for preservation of these families.

The basic problem of homeless families cannot be solved by physicians. Provision of adequate housing, job retraining for the parents, and mental health and social services are necessary to prevent homelessness from occurring. Physicians can have an important role in motivating society to adopt the social policies that will prevent homelessness from occurring by pointing out the likelihood that these homeless children will become burdens both to themselves and to society if their special health needs are not met.

RUNAWAY AND THROWN-AWAY CHILDREN

The number of runaway and thrown-away children and youths are estimated at about half a million, and several hundred thousand of these children have no secure and safe place to stay. Teenagers make up most of both groups. The usual definition of a runaway is a youth younger than 18 yr who is gone for at least one night from his or her home without parental permission. Most runaways leave home only once, stay overnight with friends, and have no contact with the police or other agencies. This group is no different from their “healthy” peers in psychologic status. A smaller but unknown number become multiple or permanent “runners” and are significantly different from the one-time runners. Thrown-aways include children directly told to leave the household, children who have been away from home and are not allowed to return, abandoned or deserted children, and children who run away but whose caretaker makes no effort to recover them or does not care if they return.

The same constellation of causes common to many of the other special-risk groups is characteristic of permanent runaways. These causes include environmental problems (family dysfunction, abuse, poverty), as well as personal problems of the young person (poor impulse control, psychopathology, substance abuse, or school failure). Thrown-aways experienced more violence and conflicts within their families. The reason why one child enters the group of runaways while another child enters foster care, the juvenile justice system, or mental health systems is not clear.

The minority of runaway youths who become homeless street people have a high frequency of problem behaviors. Three quarters engage in some type of criminal activity and half engage in prostitution as a means of support. A majority of permanent runaways have serious mental problems; more than one third are the product of families who engage in repeated physical and sexual abuse. These children also have a high frequency of

medical problems, including traditional infections, hepatitis, sexually transmitted diseases, and drug abuse. Although runaways usually distrust most social agencies, they will come to and use medical services. Thus, medical care may become the point of re-entry into mainstream society and the path to needed services.

Services for permanent runaways and thrown-aways need to be comprehensive and should include social, psychiatric, foster home, drug detoxification, and more traditional medical services. The only approach that has been successful has been long-term team efforts by people who develop the trust of runaway youths and then can help them to work out a better solution to their problems than by running away, drug use, and prostitution.

Although legal considerations involved in the treatment of homeless minor adolescents may be significant, most states, through their “Good Samaritan” laws and definitions of emancipated minors, authorize treatment of homeless youths. Physician liability is based on the usual malpractice standards. Legal barriers should not be used as an excuse to refuse medical care to runaway or thrown-away youths.

The Runaway Youth Act, Title III of the Juvenile Justice and Delinquency Prevention Act of 1974 (Public Law 93-414) and its amended version (Public Law 95-509) have supported shelters and provide a toll-free 24-hr telephone number (1-800-621-4000) for youths who wish to contact their parents or request help after having run away.

Parents who seek a physician's advice about a runaway child should be asked about the child's history of running away, the presence of family dysfunction, and personal aspects of the child's development. If the youth contacts the physician, he or she should be examined and the youth's health status should be assessed, as well as his or her willingness to return home. If it is not feasible for the youth to return home, foster care, a group home, or an independent living arrangement should be sought by referral to a social worker or a social agency.

INHERENT STRENGTHS IN VULNERABLE CHILDREN AND INTERVENTIONS

By age 20–30 yr, many children who were at special risk will have made moderate successes of their lives. Furstenberg's study of teenage mothers and Werner's study of children in Kauai, most of whom were born prematurely or in poverty, demonstrate that by this age, the majority in each study had defied the odds and made the transition to stable marriages and jobs and were accepted by their communities as responsible citizens.

Certain biologic characteristics are associated with success over the long term, such as being born with an accepting temperament. Avoidance of additional social risks is even more important. Premature infants or preadolescent boys with conduct disorders and poor reading skills, who must also face a broken family, poverty, frequent moves, and family violence, are at much greater risk than children with only one of these handicaps. Perhaps most important are the protective buffers that have been found to enhance children's resilience because these can be aided by an effective health care system and community. Children generally do better if they can

gain social support, either from family members or from a nonjudgmental adult outside the family, especially an older mentor or peer. Providers of medical services should develop ways to “prescribe” supportive “other” persons for children who are at risk and isolated. Promotion of self-esteem and self-efficacy seems to be a very central factor in protecting against risks. It is essential to promote competence in some area of these children's lives.

Providers of medical services need the patience to work over a long time frame and the willingness to accept limited improvement. In addition, prediction of the consequences of risk is never 100% accurate. Health professionals as well as families should have hope. However, the confidence that, even without aid, many such children will achieve a good outcome by age 30 yr does not justify ignoring or withholding services from them in early life. It should teach us how to focus our resources on those most in need and provide a basis for hope in individual cases.

Programs that seem to work for high-risk children have a similar group of characteristics. A team is needed, because it is rare for one individual to be able to provide the multiple services needed for high-risk children. At the same time, successful programs are characterized by at least one caring person who can make personal contact with these children and their families. Most successful programs are relatively small (or are large programs divided up into small units) and nonbureaucratic but are intensive, comprehensive, and flexible. They work not only with the individual but also with the family, school, community, and even at broader societal levels. In addition, generally the earlier the programs are started, in terms of the age of the children involved, the better is the chance of success. It is also important for services to be continued over a long period.

Part 6 - Nutrition

153

Chapter 40 - Nutritional Requirements

William C. Heird

The dramatic growth of infants during the 1st yr of life (e.g., a three-fold increase in weight and a two-fold increase in length) and continued growth, albeit at lower rates, from 1 yr of age through adolescence impose unique nutritional needs (see Chapters 7–16). Moreover, these needs for growth are superimposed on relatively high maintenance needs incident to the higher metabolic and nutrient turnover rates of infants and children vs. adults. Furthermore, because the rapid rates of growth are accompanied by marked developmental changes in organ function and composition, failure to provide adequate nutrients during this time is likely to have adverse effects on development as well as growth. Unfortunately, provision of these special nutrient needs, particularly during early life, is complicated by the young infant's lack of teeth and immature digestive and metabolic processes.

Recommended (or reference) intakes of most nutrients have been established, and these appear to fulfill the unique nutritional needs of the infant and young child. The most recent recommendations of the Food and Nutrition Board, National Academy of Sciences (1–5), for the 0–6 mo old infant, the 6–12 mo old infant, the 1–3 yr old child, and the 4–8 yr old child are summarized in Table 40–1 . Some of these recommendations are discussed briefly in this chapter. Other aspects of nutrition relevant to each age group, including how to provide the recommended or reference intakes, are discussed in Chapter 41 .

Requirement vs. Recommended Intake.

The Estimated Average Requirement (EAR) of a specific nutrient is the amount of that nutrient that results in some predetermined physiologic end-point. In infants, this

end-point is usually maintenance of satisfactory rates of growth and development and/or prevention of specific nutritional deficiencies. The EAR is usually defined experimentally, often over a relatively short period and in a relatively small study population. Thus, the EAR, by definition,

Estimated minimum requirement (for sodium, chloride, and potassium) from Recommended Dietary Allowances, 10th edition.

* *RDA.*

† *Adequate intake (e.g., for infants <1 yr of age; this is the mean intake of normal breast-fed infants).*

meets the needs of roughly half of the population in which it was established but not the needs of the other half. For some, it may be excessive, whereas, for others, it may be inadequate.

The recommended daily allowance (RDA) of a specific nutrient, on the other hand, is the intake of that nutrient deemed to meet the “requirement” for that nutrient by most healthy members of a population. If the EAR of a specific nutrient is known and is normally distributed within the population in which it was established, the RDA for that nutrient is the mean requirement (i.e., the EAR) plus 2 standard deviations. Because the requirements of many nutrients are not normally distributed, other considerations of population variability frequently are necessary. For example, if the “requirement” appears to be adequate for most of the study population, the RDA may be less than the requirement plus 2 standard deviations. RDAs are useful for assessing the nutrient intakes of individuals or groups but not for ascertaining the adequacy, inadequacy, or excess of an individual subject's intake of a specific nutrient.

Because the mean requirement of many nutrients is not known with certainty, it is often difficult to establish a valid RDA. This is particularly true for infants. In recognition of the lack of a valid EAR for most nutrients and the uncertainty of an RDA based on limited information, the latest recommendations of the Food and Nutrition Board, National Academy of Sciences, are Dietary Reference Intakes

(DRIs). These include RDAs for those nutrients for which an EAR has been established; and a RDA, therefore, can reliably be established as well as other "reference intakes." The other reference intakes include Adequate Intake (AI) and Tolerable Upper Intake Level (UL).

The AI of a specific nutrient is a recommended daily intake based on the observed or approximated intake of that nutrient by a group of healthy individuals. It is used when an RDA cannot be established, but it is not synonymous with an RDA. The content of a specific nutrient in the average volume of milk consumed by healthy, normally growing, breast-feeding infants is considered an adequate intake of that nutrient for infants younger than 6 mo of age. This definition is consistent with national and international recommendations for exclusive breast-feeding for the first 4–6 mo of life. For the 6–12 mo old infant, the AI of most nutrients is set at the amount of the nutrient in the average volume of human milk plus the average amount of complementary foods consumed by healthy, normally growing 6–12 mo old infants. The EAR of a few nutrients has been established for older children. These were determined directly or by extrapolation from data obtained in adults or older children. For these, an RDA can be established. However, this is impossible for most nutrients and, for these, an AI based on the mean intake of apparently "normal" infants and/or children has been established.

The Tolerable Upper Intake Level (UL) is the highest daily intake of a specific nutrient that is likely to pose no risk. It is not a recommended level of intake but, rather, an aid for avoiding excessive intake and adverse effects secondary to such intake. ULs of those nutrients for which one has been or can be established are summarized in Table 40–2 .

THE 0–6 MO OLD INFANT

Energy.

Expressed per unit of body weight, the normal infant requires approximately three times more energy than the adult. This reflects primarily the higher metabolic rate of the infant vs. the adult and the infant's special needs for growth and development. The inefficient intestinal absorption of the infant vs. the adult contributes only minimally to the higher energy needs of the infant fed human milk or modern infant formulas.

The currently recommended energy intakes are based on total energy expenditure measured by the doubly labeled water technique plus a reasonable allowance for growth based on changes in body composition. These are about 15% lower than the previous RDA or established requirements.

There is no evidence that either carbohydrate or fat is a superior source of energy. Sufficient carbohydrate to prevent ketosis and/or hypoglycemia is required (~5.0?g/kg/24?hr), as is enough fat to provide essential fatty acid requirements (0.5–1.0?g/kg/24?hr of linoleic acid plus a smaller amount of a-linolenic acid). Currently, there is concern that infants also require long-chain, polyunsaturated fatty acids (LC-PUFA). These fatty acids are more than 18 carbons in length and have two or more double bonds. Those that are most relevant to infant nutrition are arachidonic acid (20:4?6) and docosahexaenoic (22:6?3) acid. (By convention, the first number indicates the length of the carbon chain, the number after the colon indicates the number of double bonds, and ?6 and ?3 indicate the site of the first double bond from the noncarboxyl [?] end of the molecule.) These two fatty acids are the most prevalent ?6 and ?3 fatty acids, respectively, in the central nervous system, and the latter comprises up to 40% of the fatty acid content of retinal photoreceptor membranes. Both are synthesized by the same series of desaturation and elongation reactions from the essential fatty acids linoleic (18:2?6) and a-linolenic (18:3?3) acid.

Although infants can convert linoleic and a-linolenic acid, respectively, to arachidonic acid and docosahexaenoic acid, the content of arachidonic and docosahexaenoic acid in plasma and erythrocyte lipids is lower in formula-fed vs. breast-fed infants, and autopsy studies show that the low erythrocyte lipid content of docosahexaenoic acid, but not arachidonic acid, is accompanied by a lower concentration in brain. These differences are assumed to reflect the presence of LC-PUFA in human milk but not formula, suggesting that the synthetic pathway, while intact, does not synthesize enough LC-PUFA. The generally better visual and cognitive development of breast-fed vs. formula-fed infants also has been attributed to the presence of LC-PUFA in human milk but not formula.

Because human milk contains a number of factors other than LC-PUFA that might be important for development, the specific role of LC-PUFA in visual and cognitive development of infants cannot be determined by studies of formula-fed vs. breast-fed infants. Moreover, there are major psychosocial and socioeconomic differences between mothers who choose breast-feeding vs. formula feeding. Thus, over the past decade, many studies have addressed differences in visual function and/or neurodevelopmental status of infants fed LC-PUFA–supplemented vs. unsupplemented formulas. Some of these have shown distinct advantages of LC-PUFA supplementation, but others have not; and the reasons for the different findings are not clear. A meta-analysis of the available data concerning the effect of LC-PUFA supplementation on visual function of term infants shows that supplementation confers advantages at some, but not all, ages. When detected, the magnitude of the advantage equates to approximately one line on a Snellen chart. No such analysis of data concerning neurodevelopmental outcomes, some positive and some negative, is available.

Although a report prepared to advise the U.S. Food and Drug Administration concerning desirable nutrient contents of term infant formulas marketed in the United States did not recommend inclusion of LC-PUFA, similar groups in other countries have advised supplementation. Formulas containing arachidonic and docosahexaenoic acid have been available for some time in many parts of the world and are now available in the United States. These appear to be safe and, in theory, may confer developmental advantages.

In total, the specific needs for carbohydrate and fat, including LC-PUFA, amount to no more than 30?kcal (125.5?kJ)/kg/24?hr, or only about a third of the 0–6 mo old infant's total energy need. Whether the remainder should be comprised predominantly of carbohydrate, fat, or equicaloric amounts of each is not known. Human milk and most currently available formulas contain roughly equicaloric amounts of each. Because a higher percentage of energy as carbohydrate will increase osmolality

NA = Not available; ND = data insufficient to establish a tolerable upper intake level.

and a higher percentage as fat may exceed the limited ability of the infant to digest and absorb fat, roughly equicaloric amounts of each seems appropriate.

Protein.

The protein requirement of the normal infant also is greater per unit of body weight than that of the adult. In addition, it is thought that the infant requires a higher proportion of essential amino acids than the adult. These include the amino acids recognized as essential (or indispensable) for the adult (i.e., leucine, isoleucine, valine, threonine, methionine, phenylalanine, tryptophan, lysine, and histidine) as well as cysteine, tyrosine, and, perhaps, arginine. The need for cysteine is thought to be secondary to delayed development of hepatic cystathionase activity; this key enzyme in conversion of methionine to cysteine does not reach adult levels until at least 4 mo of age. The reason for the infant's apparent need for tyrosine is not clear; the hepatic activity of phenylalanine hydroxylase, the rate-limiting enzyme for conversion of phenylalanine to tyrosine, is at or near adult levels early in gestation. It also appears that even preterm infants can convert phenylalanine to tyrosine.

In general, human milk protein and all proteins currently used in infant formulas contain adequate amounts of all essential amino acids, including cysteine, tyrosine, and arginine. Furthermore, the sum of the highest estimates of the requirement of each amino acid is considerably less than the overall protein requirement. However, the required intake of a specific protein depends on its quality, which is usually defined as how closely its amino acid pattern resembles that of human milk. The overall quality of a specific protein can be improved by supplementing it with the essential amino acid(s) that result(s) in its quality being low, i.e., the limiting amino acid. Native soy protein, for example, has insufficient methionine, but when it is

fortified with methionine its quality approaches that of bovine milk protein.

Although the amino acid composition of human milk protein is considered ideal, the total protein content of human milk, though quite variable, averages only approximately 1.0?g/dL. Thus, on average, about 200?mL/kg/24?hr must be ingested to meet the current RDA for protein (i.e., 2.0–2.2?g/kg/24?hr). However, because few, if any, breast-fed infants develop protein deficiency, the high quality and easy digestibility of human milk protein obviously compensate for any quantitative deficiency. Bovine milk protein and modern preparations of soy protein, the protein sources of most infant formulas, also are very high quality proteins. Furthermore, if properly processed, these proteins are utilized nearly as well, perhaps as well, as human milk protein. Thus, the amount of these proteins needed to support normal growth is likely to be only minimally, if at all, higher than the amount of human milk protein needed. This possibility is reflected by the protein intakes recommended recently by an International Dietary Energy Consultative Group (IDECG). The “safe” protein intake recommended by this group is approximately 30% higher than the estimated requirement but considerably less than the most recent RDA, particularly for infants older than 3 mo of age. The new AI for protein, released by the Food and Nutrition Board, National Academy of Sciences, is based on the intake of exclusively breast-fed infants.

Electrolytes, Minerals, and Vitamins.

Estimated safe and adequate intakes of sodium, chloride, and potassium have been available for some time (see Table 40–1), and infants who receive these intakes experience few problems. More recently, adequate intakes of most minerals and vitamins have been recommended.

In general, these represent the amount of each nutrient in the average intake of breast milk by a healthy, normally growing, 0–6 mo old breast-fed infant.

Although the normal newborn infant is thought to have sufficient stores of iron to meet requirements for 4–6 mo, iron deficiency is common during infancy (see Chapter 447). This reflects the fact that iron stores at birth as well as the absorption of iron are quite variable. Interestingly, although human milk contains less iron than most formulas, iron deficiency is less common in breast-fed infants. Nonetheless, to prevent iron deficiency, routine iron supplementation of breast-fed infants and use of iron-fortified formulas for formula-fed infants is often recommended. The widespread use of iron-fortified formulas over the past several years is thought to have dramatically reduced the incidence of iron deficiency.

If protein intake is adequate, vitamin deficiencies are rare; if not, deficiencies of nicotinic acid and choline, which are synthesized, respectively, from tryptophan and methionine, may develop. In contrast, if bovine milk and bovine milk formulas were not supplemented with vitamin D, hypovitaminosis D would be endemic among formula-fed infants, particularly those with limited exposure to sunlight. Breast-fed infants may not be as susceptible to development of vitamin D deficiency as formula-fed infants, but routine vitamin D supplementation of breast-fed infants is often recommended. Reports of rickets in both breast-fed and formula-fed, dark-skinned infants and infants chronically protected from sunlight have led some to suggest routine vitamin D supplementation for all infants.

Routine perinatal administration of vitamin K is recommended as prophylaxis against hemorrhagic disease of the newborn (see Chapters 92 and 472). Thereafter, deficiency of this vitamin is uncommon except in infants with conditions associated with fat malabsorption.

Water.

The normal infant's absolute requirement for water probably is 75–100?mL/kg/24?hr. However, because of higher obligate renal, pulmonary, and dermal water losses as well as a higher overall metabolic rate, the young infant is more susceptible to development of dehydration, particularly with vomiting and/or diarrhea or if solute intake is high, as it is in bovine milk. Thus, intake of bovine milk before 1 yr of age is discouraged and provision of a fluid intake of 150?mL/kg/24?hr is recommended. Because human milk and common formulas are at least 90% water, the typical breast-fed infant as well as the typical formula-fed infant usually consumes this amount for the first several weeks to months of life and, hence, does not need additional water.

THE 6–12 MO OLD INFANT

The nutritional needs of the infant during the last half of the 1st yr of life are no more firmly based on experimental data than those of the younger infant. The AI for most nutrients cited for this age group by the Food and Nutrition Board, National Academy of Sciences (see Table 40–1), reflects the amount of that nutrient in the average volume of human milk consumed by the 6–12 mo old infant plus the amount in the average intake of complementary foods based on national surveys. The AI for other nutrients relies heavily on extrapolation of data obtained in older children and/or adults. These recommendations reflect the developmental differences between younger and older infants as well as the greater level of activity and somewhat slower rate of growth after 6 mo of age. Despite the lack of experimental data concerning the nutrient needs during the second 6 mo of life, the reference intakes for this age group appear to be appropriate.

The most recent EAR for energy (720?kcal [3,013?kJ]/24?hr) reflects estimates of energy needs based on measurement of energy expenditure by the doubly labeled water method and energy deposition as protein and fat (i.e., ~90?kcal [376.6?kJ]/kg/24?hr), throughout the 1st yr of life.

THE CHILD OLDER THAN 1 YR

After 1 yr of age, the child's rate of growth slows and the nutrient needs for growth consequently decrease. However, the rate of growth remains appreciable. Moreover, activity increases. Thus, on a body weight basis, nutrient needs after the 1st yr of life are only minimally less than those during the 1st yr of life (see Table 40–1).

Although the Food and Nutrition Board, National Academy of Sciences, provides reference intakes for the 1–3 yr old and the 4–8 yr old, the major physiologic reason

for differentiating between these two periods is the somewhat greater rate of increase in height between 1–3 vs. 4–8 yr of age. On the other hand, there are many practical reasons for differentiating these two periods. Children begin entering school at about 4 yr of age, and availability of reference intakes for the 4–8 yr old child makes it easier for school systems to design meals. This also makes it easier to assess the intake of individual children. In addition, a reasonable amount of data on which to establish EARs are available in this age group. Ending this period at 8 (or 9) yr of age, of course, circumvents the necessity of considering the effect of endocrine changes associated with puberty on nutrient needs.

After 2 yr of age, most children are eating the same foods as the rest of the family. Thus, after this age a diet based on an appropriate number of servings from the various food groups of the food guide pyramid, as modified for children older than 2 yr of age, will provide adequate amounts of most if not all nutrients. Table 40–3 summarizes the recommended number of servings from each food group as well as the size of a serving for a 4–6 yr old child. Two to 3 yr old children need the same number of servings of each food group as 4–6 yr old children, but the size of each serving should be only about two thirds that recommended for 4–6 yr old children.

USING THE DRIs

The DRIs are useful for assessing the nutrient intake of individuals as well as groups. For the individual, the EAR can be used to examine the possibility that the reported intake of a specific nutrient is adequate or inadequate. For example, a reported intake below the EAR suggests inadequacy. However, because individual requirements vary, such an intake may or may not be inadequate for an individual subject. Similarly, a reported intake of a specific nutrient that is greater than the EAR suggests that the intake is likely to be adequate but, because of individual differences in requirements, it may not be.

TABLE 40-3 -- **Use of Food Pyramid Guidelines**

Food Group	Serving Size*	Servings/Day
Grain	1 slice bread	6
	½ cup rice (cooked)	
	½ cup pasta	
Vegetables	½ cup raw or cooked	3
	1 cup leafy	
Fruit	¼ medium melon	2
	1 whole fruit	
	¾ cup juice	
	½ cup canned	
	½ cup berries, grapes	
Milk	1 cup milk, yogurt	2
	2?oz cheese	
Meat	2–3?oz cooked, lean	2
	½ cup dried beans†	
	1 egg†	
	2 Tbsp peanut butter	
Fats/sweets		Limit

These serving sizes are for 4–6 yr old children; serving sizes for 2–3 yr old children, except for milk, should be about two thirds of these.

† *These amounts are equal to 1?oz lean meat; two servings are equal to one meat serving.*

Assessment of a reported intake against the AI or RDA, if one has been established, is likely to be more useful, particularly for assessing the adequacy of a reported intake. An intake equal to or greater than the AI or RDA is likely to be adequate. However, an intake below the AI or RDA also may be adequate for many individuals.

The EAR can be used to estimate the prevalence of inadequate intakes in a group (e.g., the percentage of the group that has an intake below the EAR). Similarly, mean intakes at the AI imply a low prevalence of inadequate intakes. Individual or mean group intakes above the UL suggest the risk of adverse effects for both the individual and the group.

For planning purposes, either for an individual or for a group, the aim should be to

achieve intakes equal to the AI or the RDA and to avoid intakes above the UL. This helps ensure adequate intakes of all nutrients with minimal risk of adverse effects due to excessive intakes.

Using the reference intakes just described requires an accurate assessment of the usual intake. For individuals, this is best obtained from a food diary maintained over a period of several days. Any reasonable, statistically valid estimate of the mean intake of groups can be used.

Chapter 41 - The Feeding of Infants and Children

William C. Heird

The establishment of feeding practices that are comfortable and satisfying for both the mother and the infant is crucial for the emotional well-being of both and for ensuring adequate nutrient intakes for the infant. Maternal feelings are readily transmitted to the infant and are a major determinant of the emotional setting in which feeding takes place. Thus, mothers who are tense, anxious, irritable, easily upset, or emotionally labile are more likely to experience a difficult feeding relationship. However, appropriate guidance and support from an empathetic and experienced relative, friend, lactation consultant, or physician can increase such a mother's confidence, which, in turn, makes her more relaxed and increases the likelihood of establishing successful feeding practices, not only during infancy but throughout childhood and beyond.

FEEDING DURING THE FIRST 6 MO OF LIFE

Feedings should be initiated as soon after birth as possible, depending on the infant's ability to tolerate enteral nutrition. This not only maintains normal metabolism during the transition from fetal to extrauterine life but also promotes maternal-infant bonding. Most infants can start breast-feeding shortly after birth, almost always within 4–6?hr. Hence, mothers who wish to initiate breast-feeding in the delivery room and continue to do so on a demand basis should be supported in doing so. However, if any question about the infant's tolerance of feeding arises, feedings should be withheld until the infant is carefully evaluated. It if appears that feedings must be withheld for several hours, parenteral fluids should be administered.

The successful feeding of infants requires practical interpretation of specific nutritional needs and the wide variability among normal infants in appetite and behavior regarding food. For example, the time required for an infant's stomach to empty may vary from 1–4?hr or more during a single day. Thus, the infant's desire for food will vary at different times of the day. Ideally, the feeding schedule established should be based on this reasonable “self-regulation” by the infant. However, the establishment of this “self-regulation” is not immediate and considerable variation in the time between feedings and in the amount taken per feeding is to be expected during the first few weeks of life. Most infants will have established a suitable and reasonably regular schedule by 1 mo of age.

By the end of the 1st wk of life, most healthy infants will want 6–9 feedings/24?hr. Some will take enough at one feeding to be satisfied for as long as 4?hr, but others will want to be fed as often as every 2–3?hr. In general, breast-fed infants prefer shorter feeding intervals than formula-fed infants. Most infants will be taking 80–90?mL per feeding by the end of the 1st wk of life. Feeding can be considered to have progressed satisfactorily if the infant is no longer losing weight by the end of the 1st wk of life and is gaining weight by the end of the 2nd wk. Although most infants will awaken for a middle-of-the-night feeding until 3–6 wk of age, some never desire this feeding and others continue to desire it well beyond 3–6 wk of age. Between 4–8 mo of age, many infants will lose interest in the late evening feeding; and by 9–12 mo of age, most will be satisfied with 3 meals/day plus snacks. However, not all infants conform to these general guidelines. Individual feeding needs are quite variable, and not all infants can be expected to fit the same pattern.

It is important to appreciate that infants cry for reasons other than hunger and that they do not need to be fed every time they cry. Those who awaken and cry consistently at short intervals may not be receiving enough milk, or they may have discomfort from some cause other than hunger (e.g., too much clothing; colic; soiled, wet, or uncomfortable diapers; swallowed air (“gas”); an uncomfortably hot or cold environment; illness). Some infants cry to gain sufficient or additional attention, whereas others become indifferent to lack of attention. Some cry because they simply need to be held. Those who stop crying as soon as they are picked up or held usually do not need food. Those who continue to cry when held and when food is offered should be carefully evaluated for other causes of distress. The habit of offering frequent, small feedings or holding and feeding to pacify all crying should not be allowed to develop.

At the same time, satisfying the infant's true hunger as it is expressed has several advantages. This allows physiologic requirements to be met promptly. Moreover, the infant is less likely to associate prolonged crying and discomfort with feeding and, also, is less likely to develop eating practices such as gulping an entire feeding or taking small amounts too frequently. Most infants establish a regular feeding schedule that permits the family to resume normal functioning within a few weeks after the infant's birth. If not, individual feedings or the whole day's schedule can be moved ahead or delayed sufficiently to avoid conflicts with necessary family activities.

Some mothers will not understand the goals of infant “self-regulation,” and some will misinterpret the physician's instructions or be unable to adjust to the infant's regimen. These as well as orderly, overanxious, and compulsive parents may do better with more specific instructions for the infant's feeding activities.

The postpartum period is a time of great anxiety and insecurity, particularly for the first-time mother who often is temporarily overwhelmed by the responsibilities of motherhood. Thus, it is important for the physician to set aside sufficient time shortly after birth to address the questions and concerns of inexperienced or uncertain mothers. Ideally, these anticipatory guidance sessions should include fathers and

other household members. Knowing the personalities and expectations of both parents is invaluable in helping avert physical and psychologic problems centered on feeding. Also, because parental misconceptions and confusion about the dietary and satiety needs of infants are often the basis for abnormal parent-child relations, appropriate counseling can help avoid or lessen these problems.

Breast-Feeding vs. Formula-Feeding.

One of the first decisions a new mother must make—ideally, some time before the infant is born—is whether the infant will be breast-fed or formula-fed. Human milk is uniquely adapted to the infant's needs and, hence, is the most appropriate milk for the human infant. Breast-feeding also has practical and psychologic advantages. Thus, all mothers should be encouraged to at least consider breast-feeding her baby.

ADVANTAGES OF BREAST-FEEDING.

Breast milk is the natural food for full-term infants during the first months of life. It is always available at the proper temperature and requires no preparation time. It is fresh and free of contaminating bacteria, thereby reducing the chances of gastrointestinal disturbances. Although there is little if any difference in mortality rates between formula-fed and breast-fed infants receiving good care, the protective effects of breast milk against enteric and other pathogens result in less morbidity. These effects are particularly important in developing countries or any locality without a safe supply of potable water and effective methods for disposal of human waste.

Breast-feeding is associated with fewer feeding difficulties incident to allergy and/or intolerance to bovine milk. These include diarrhea, intestinal bleeding, occult melena, “spitting up,” colic, and atopic eczema. Breast-fed infants also appear to have a lower frequency of certain allergic and chronic diseases in later life than formula-fed infants.

Human milk contains bacterial and viral antibodies, including relatively high concentrations of secretory IgA that prevents microorganisms from adhering to the intestinal mucosa. It also contains substances that inhibit growth of many common viruses. Antibodies in human milk are thought to provide local gastrointestinal immunity against organisms entering the body via this route. They probably account, at least partially, for the lower incidence of diarrhea as well as otitis media, pneumonia, bacteremia, and meningitis during the 1st yr of life in infants who are breast-fed exclusively vs. formula-fed for the first 4 mo of life.

Macrophages in human milk may synthesize complement, lysozyme, and lactoferrin. In addition, breast milk contains lactoferrin, an iron-binding whey protein that is normally about one-third saturated with iron and has an inhibitory effect on the growth of *Escherichia coli* in the intestine. The lower pH of the stool of breast-fed infants is thought to contribute to the favorable intestinal flora of infants fed human milk vs. formula (i.e., more bifidobacteria and lactobacilli; fewer *E. coli*), which helps protect against infections caused by some species of *E. coli*. Human milk also contains bile salt–stimulated lipase, which kills *Giardia lamblia* and *Entamoeba histolytica.* Transfer of tuberculin responsiveness by breast milk suggests passive transfer of T-cell immunity.

Milk from the mother whose diet is sufficient and properly balanced will supply all the necessary nutrients except, perhaps, fluoride and, after several months, vitamin D. If the water supply is not adequately fluoridated (=0.3?ppm), the breast-fed infant should receive at least 10?µg of fluoride daily for the first 6 mo of life; thereafter, the fluoride intake should approximate the adequate intake (see Table 40–1). If the maternal vitamin D intake is inadequate and the infant's exposure to sunlight is limited (e.g., dark-skinned infants and infants who are chronically protected from sunlight), 10?µg/24?hr of vitamin D is recommended. The iron content of human milk is somewhat low. However, most normal infants have sufficient iron stores for the first 6 mo of life. Moreover, human milk iron is well absorbed. Nonetheless, by 4–6 mo of age, the breast-fed infant's diet should be supplemented with iron-fortified complementary foods or a ferrous iron preparation.

The vitamin K content of human milk also is low and may contribute to hemorrhagic disease of the newborn. Parenteral administration of 1?mg of vitamin K_1 at birth is recommended for all infants, and this is especially important for those who will be breast-fed.

The psychologic advantages of breast-feeding for both mother and infant are well recognized. The mother is personally involved in the nurturing of her infant, resulting both in a feeling of being essential and a sense of accomplishment while the infant is provided with a close and comfortable physical relationship with the mother.

The resumption of menstruation should not deter continued breast-feeding. However, temporary behavior changes of the mother and/or the baby may call for reassurance. Pregnancy does not necessitate immediate cessation of nursing, but the combined demands of supplying milk to the infant and nutrients to the developing fetus are formidable, necessitating special attention to maternal nutrition.

Transmission of HIV by breast-feeding is well documented. Thus, if safe alternatives are available, breast-feeding by HIV-infected mothers is not recommended. However, in many developing countries, breast-feeding may be crucial to infant survival; if so, the risk of HIV transmission by breast-feeding may be less than the risks of other feeding methods. The World Health Organization recommends that breast-feeding be continued, even in areas of high endemic rates of HIV infection, unless safe infant formula is readily available. This reflects the belief that the risk of formula-feeding in many developing countries is significantly greater than the risk of HIV infection with breast-feeding.

Cytomegalovirus (CMV), human T-cell lymphotropic virus type 1, rubella virus, hepatitis B virus, and herpes simplex virus also have been demonstrated in breast milk. Of these, the presence of CMV is the most troublesome. About two thirds of seronegative breast-fed infants may become infected with CMV. In term infants, this appears to be without symptoms or sequelae, but the risk of infection in preterm infants may be substantially greater. Thus, the use of fresh donor milk for feeding preterm infants is contraindicated unless the milk is known to be CMV negative.

Evidence of breast milk transmission of other viruses is rare. However, vesicles have

been noted in the mouth of infants

whose mothers' milk contained herpes simplex virus. Thus, nursing women with active herpes simplex lesions should observe scrupulous handwashing technique and should avoid nursing if there are active lesions on or near the nipple.

Although hepatitis B virus has been isolated from maternal milk, the predominant means of mother-infant transmission of this virus appears to be at delivery. Active immunization of the infant within the first 24?hr of life coupled with administration of specific high-titer hepatitis B immune globulin and a follow-up active vaccination should permit the mother who is infected with hepatitis B to nurse with minimal risk to the infant. If a nursing mother acquires hepatitis B, the infant should receive the accelerated protocol of immunization (see Chapter 282).

PREPARATION OF THE PROSPECTIVE MOTHER FOR BREAST-FEEDING.

Most women, if encouraged and protected from discouraging experiences and comments while the secretion of breast milk is becoming established, can successfully breast-feed their infant. The physician interested in helping the prospective mother breast-feed successfully should discuss the advantages of breast-feeding with her as early as the midtrimester of pregnancy or whenever the mother begins planning for her infant. Many mothers who are ambivalent toward breast-feeding are able to nurse successfully if they are reassured and supported. However, if the mother adamantly rejects the suggestion that she nurse her infant, overpersuasion may be detrimental to mother-infant relationships.

Factors that are conducive to successful breast-feeding include good health, a proper balance of rest and exercise, freedom from worry, early and sufficient treatment of any intercurrent disease, and adequate nutrition. Retracted and/or inverted nipples are detractors but not contraindications to breast-feeding. Retracted nipples usually benefit from daily manual breast-pump traction during the latter weeks of pregnancy, and truly inverted nipples may be helped by the use of milk cups, starting as early as the 3rd mo of pregnancy.

If the mother's diet is adequate, she need not gain or lose weight while breast-feeding. Nursing will help the uterus return to its normal size sooner and, also, may help the mother return to her prepregnancy weight sooner. Many women must be reassured that breast tone will be preserved by the use of a properly fitted brassiere to support the breasts, especially before delivery and during the nursing period.

ESTABLISHING AND MAINTAINING THE MILK SUPPLY.

The most satisfactory stimulus to the secretion of human milk is regular and complete emptying of the breasts. Thus, efforts should be directed toward the early establishment of normal, vigorous nursing, even during the first few days after birth when there appears to be little, if any, milk. Breast-feeding should begin as soon after delivery as the conditions of the mother and the infant permit, preferably within the 1st?hr or so. Infants who cannot be fed on demand should be brought to the mother for feeding about every 3?hr during the day and night. Once lactation is well established, most mothers are capable of producing more milk than their infant needs.

Appropriate care for tender or sore nipples should be instituted before severe pain from abrasions and cracking develops. Exposing the nipples to air; applying pure lanolin; avoiding soap, alcohol, and tincture of benzoin; changing disposable nursing pads lining the brassiere cups frequently; nursing more frequently; manually expressing milk; nursing in different positions; and keeping the breast dry between feedings are recommended. If nipple tenderness is sufficient to make the mother apprehensive, the milk-ejection reflex may be delayed. This leads to frustration of the infant and increasingly vigorous nursing, which further injures the nipple and areolar area. Nipple shields may be helpful in these situations.

The first 2 wk after birth are crucial for establishing breast-feeding. Daily weight gains of the infant, while important for ascertaining the volume of milk produced, should not be overly emphasized during this time. In addition, supplemental bottle feedings to achieve weight gain should be limited because these may compromise attempts at breast-feeding.

Although the difference between breast and bottle nipples may confuse the infant, this is usually not a serious problem. It is perfectly satisfactory to have the mother pump her breasts and feed the infant breast milk via a bottle for the first 1–2 wk. Then, when she is relaxed and less anxious, she can attempt breast-feeding one or two times daily until she and the infant have achieved a successful nursing routine. The additional pumping will usually increase milk production, thereby helping to ensure an adequate supply. Even after nursing is well established, it may be appropriate for the mother to pump extra milk and store it (in a freezer for up to 1 mo or refrigerator for up to 24?hr) for use when she is not available. This allows the mother some freedom and, at the same time, allows the father or other caregivers to be more involved in the infant's feeding and care.

Lactation usually is not well established before the mother is discharged from the hospital, and the excitement of going home may impede an initially successful in-hospital nursing experience. It is wise to anticipate this possibility and discuss it with the mother. Providing her with enough formula for a few complementary feedings may prevent discouragement that might prejudice further nursing.

No factor is more important for successful breast-feeding than a happy, relaxed state of mind. Mothers may worry that their infants are abnormal when they cry, are drowsy, sneeze, or regurgitate milk. They are often upset by any suggestion that their milk may be lacking in quantity or quality, and they may be disturbed by the scanty supply of colostrum, nipple tenderness, and the fullness of the breasts on the fourth or fifth day after delivery. Many mothers do not feel comfortable when trying to nurse in an open ward or, even, with another person in the room. Many also may worry about what is going on at home while they are in the hospital or about what is going to happen when they arrive home. An alert physician recognizes and appreciates these worries, particularly if the infant is a first born, and provides tactful reassurance and explanations that minimize worry and enhance the likelihood of successful breast-feeding. The support plan for individual mothers, of course, must

include consideration of social and cultural factors.

HYGIENE.

Proper hygiene will help prevent irritation and infection of the nipples caused by prolonged initial nursing, maceration from wetness of the nipple, or rubbing of clothing.

The breasts should be washed at least once a day. If soap appears to dry the nipple and areolar area, a milder, nondrying soap should be substituted or use of soap should be temporarily discontinued. The nipple area should be kept as dry as possible.

Many mothers are more comfortable wearing a properly fitted brassiere day and night. If doing so, plastic liners should be removed and a commercially available absorbent pad or clean cloth should be placed inside the brassiere to absorb any leaked milk.

MATERNAL DIET AND OTHER FACTORS.

The breast-feeding mother's diet should contain enough calories and other nutrients to compensate for those secreted in the milk as well as for those required to produce it. A varied diet sufficient to maintain weight and generous in fluid, vitamins, and minerals is important. Weight-reducing diets should be avoided, particularly while the infant is exclusively breast-fed. Milk is an important component of the mother's diet, but it should not replace other essential foods. If the mother is allergic to milk or dislikes it, her diet should be supplemented with 1?g calcium daily. Daily fluid intake should approximate 3?qt.

Ingestion of some foods (e.g., berries, tomatoes, onions, members of the cabbage family, chocolate, spices, and condiments) by the mother may occasionally cause gastric distress or loose stools in the infant. However, no food need be withheld from

the mother unless it is known to cause, or is strongly suspected of causing, distress to the infant.

Nursing mothers should not take drugs unless they are absolutely necessary. Many preparations are harmful to the neonate, and many have not been evaluated. Antithyroid medications, lithium, anticancer agents, isoniazid, recreationally abused drugs, and phenindione are contraindicated for the breast-feeding mother. If any of these agents or diagnostic radiopharmaceuticals, chloramphenicol, metronidazole, sulfonamides, and/or anthraquinone-derivative laxatives are required, temporary cessation of breast-feeding should be considered. Nursing mothers should not eat fish from waters contaminated with polychlorinated biphenyls or other substances (e.g., mercury). Smoking cigarettes and drinking alcoholic beverages should be discouraged during breast-feeding. It is important for the breast-feeding mother to avoid fatigue. However, she should exercise sufficiently to promote her sense of physical well-being.

TECHNIQUE OF BREAST-FEEDING.

Breast-feeding sometimes becomes impossible simply because the attending physician fails to recognize that the difficulties are in the feeding technique. Hence, it is important to review the technical aspects of breast-feeding with the mother, particularly the mother who has not breast-fed before.

At feeding time, the infant should be hungry, dry, and neither too cold nor too warm. He or she should be held in a comfortable, semi-sitting position to prevent vomiting with eructation. The mother, too, should be comfortable and completely at ease. A moderately low chair with an armrest is preferable, and a low stool for resting her foot and raising her knee on the nursing side is advantageous. The infant should be supported comfortably with the face held close to the mother's breast by one arm and hand while the other hand supports the breast, making the nipple easily accessible to the infant's mouth without obstructing nasal breathing. The infant's lips should engage considerable areola as well as nipple.

Success in breast-feeding depends, in large part, on the adjustments made during the first few days of life. Difficulties often result from attempts to adapt the infant to a nursing procedure rather than designing a procedure that satisfies the infant. Most problems can be avoided by conforming to the infant's spontaneous pattern. If the infant is breast-fed when hungry and his or her appetite is satisfied, the fundamental requirements are met.

Several reflexes or behavior patterns that facilitate breast-feeding are present at birth. These include the rooting, sucking, swallowing, and satiety reflexes. The *rooting reflex* is the first to come into play. When the infant smells milk, he or she moves the head in an attempt to find the source of the smell. If the cheek is touched by a smooth object (e.g., the mother's breast), the infant will turn toward that object and open his or her mouth in anticipation of grasping the nipple (i.e., rooting with the mouth for the nipple).

The infant's rooting reflex brings the entire areolar area into the infant's mouth, and contact of the nipple against the infant's palate and posterior tongue elicits sucking, while the buccal fat pads help keep the nipple in place. This *sucking reflex* is a process of squeezing the sinuses of the areola rather than simply sucking on the nipple, as is required for bottle-feeding. Finally, milk in the infant's mouth triggers the *swallowing reflex.*

The breast-feeding infant's sucking results in afferent impulses to the mother's hypothalamus and, then, to both anterior and posterior pituitary. Prolactin release from the anterior pituitary stimulates milk secretion by the cuboidal cells in the acini or alveoli of the breast while secretion of oxytocin by the posterior pituitary results in contraction of the myoepithelial cells surrounding the alveoli deep in the breast and, in turn, “squeezes” milk into the larger ducts, where it is more easily available to the sucking infant. When this “let down” or *milk ejection reflex* functions well, milk flows from the opposite breast as the infant begins to nurse. The reflex is often absent or erratic during periods of pain, fatigue, or emotional distress; and this is thought to be

a common cause of milk retention in women who are unsuccessful in breast-feeding.

Mothers should know that the infant who is not hungry will not search for the nipple or suck. Most infants are usually sleepy for several days after birth and, hence, are not avid suckers. By the 3rd day of life when there has been some weight loss, many mothers become anxious if the infant seems uninterested in nursing. It reassures them to learn that most healthy infants “wake up” and become good nursers by the 4th or 5th day of life. Infants whose mothers were sedated during labor usually suck at lower rates and pressures and, also, consume less milk than infants of nonsedated mothers.

Some infants will empty a breast in 5?min; others will nurse more leisurely, sometimes for 20?min or longer. Most of the milk is obtained early in the feeding (i.e., 50% in the first 2?min and 80–90% in the first 4?min). Unless the mother has sore nipples, the infant should be allowed to suck until satisfied. If the infant does not “unlatch” from the breast after a reasonable period, a finger can be inserted into the corner of his or her mouth to decrease suction and facilitate removal. The infant should not be pulled from the breast.

At the end of the nursing period, the infant should be held erect over the mother's shoulder or on her lap with or without gently rubbing or patting the back to assist in expelling swallowed air. This “burping” procedure often is necessary one or more times during the feeding as well as 5–10?min after the infant has been returned to the crib. It is an essential procedure during the early months of life but should not be overdone.

ONE OR BOTH BREASTS PER FEEDING.

The infant should empty at least one breast at each feeding; otherwise, it will not be stimulated sufficiently to refill. Both breasts should be used at each feeding in the early weeks to encourage maximal milk production. After the milk supply is established, the breasts may be alternated at successive feedings. The infant will usually be satisfied with the amount obtained from one. If milk secretion becomes too great, both breasts may be offered at each feeding but incompletely emptied, thereby decreasing milk production.

DETERMINING ADEQUACY OF MILK SUPPLY.

If the infant is satisfied after each nursing period, sleeps 2–4?hr between feedings, and gains weight adequately, the milk supply is sufficient. Infants who are “light sleepers” usually require considerable body contact with the mother during the first months of life; hence, it should not be assumed automatically that mothers of such infants have a poor milk supply. On the other hand, if the infant nurses avidly and completely empties both breasts but appears unsatisfied afterward (e.g., does not go to sleep after nursing or sleeps fitfully and awakens after 1–2?hr) and fails to gain weight satisfactorily, the milk supply is probably inadequate. The La Leche League, which establishes close relationships between successful nursing mothers and mothers needing assistance with nursing, is often helpful in such circumstances.*

In general, weighing the infant before and after every nursing to judge the adequacy of the milk supply is neither necessary nor desirable. The amount of milk that an infant takes at a single feeding ranges from one to several ounces throughout a 24?hr period and, hence, is usually unimportant with respect to daily intake. Small gains may worry the mother and, in turn, may diminish her milk supply. In addition, she may give the infant a bottle to reassure herself that the infant is getting enough to eat and the better result with the “test bottle” may discourage breast-feeding, even if she has an adequate milk supply.

* La Leche League International, 9616 Minneapolis Avenue, Franklin Park, IL 60131, has many local affiliates composed of successfully nursing mothers willing to assist other mothers desiring to nurse.

Three possibilities should be excluded before assuming that a mother cannot produce sufficient milk: (1) errors in feeding technique; (2) remediable maternal factors related to diet, rest, or emotional distress; and (3) physical disturbances of the infant that interfere with nursing or with weight gain. Infrequently, infants who seem to be nursing well may not thrive because of inadequate milk supply. In such cases, more frequent feedings may be indicated. Nursing more often than every 2?hr, however, may inhibit prolactin secretion and further decrease milk production. This usually is not a problem with feeding at 2?hr intervals. Other aids include stimulation of prolactin secretion by small doses of chlorpromazine for a few days or by devices such as the LactAid, which supplement the infant's intake.

EXPRESSION OF BREAST MILK.

Although manual expression of breast milk is useful to relieve engorgement of the breasts, the cost of battery-operated and electric breast pumps is often prohibitive. Pumping can increase milk production and relieve sore nipples because it does not cause as much nipple irritation as suckling. Breast milk can be safely stored in the freezer or refrigerator and used for feeding the infant at a later time.

SUPPLEMENTAL FEEDINGS.

Most mothers who are returning to work plan to pump enough milk while at work to feed her infant while she's at work. However, because of stress and time constraints at work, this often is not possible. These mothers should be reassured that it is acceptable to feed the infant a commercial formula during the day and continue nursing in the evening. Breast milk production will gradually decrease so that the mother is not plagued by engorged, leaking breasts but most will continue to produce enough milk for two or three feedings a day for several months.

If formula or stored breast milk is to be given after the infant has completed a breast-feeding, the warmed bottle should be available so that it can be offered immediately after the infant has been “burped.” The holes in the nipples should not be so large that the infant gets this portion of food without effort; if this happens, he or she may quickly abandon any efforts to suck adequately at the mother's breast. Some employers provide childcare at the workplace, thus enabling mothers to continue nursing successfully. Others provide convenient facilities for pumping. Such efforts by employers should be commended and encouraged.

WEANING FROM BREAST-FEEDING.

Most infants gradually reduce the volume and the frequency of breast-feedings between 6 and 12 mo of age after they become accustomed to solid foods and liquids by bottle and/or cup. As they demand less milk, the mother's supply gradually diminishes without causing discomfort from engorgement. Weaning can be initiated when mutually desired by the mother and infant by substituting formula or bovine milk by bottle or cup for part and, subsequently, for all of a breast-feeding. The breast-feedings are eventually replaced with formula, usually over several days, and the infant is weaned completely. Occasionally, an infant takes a cup as readily as a bottle. If so, the intermediate transfer from breast to bottle before transferring from bottle to cup can be avoided. These changes should be made gradually and should be a pleasant experience, not a conflict, for both the mother and the infant. Praise, loving attention, and cuddling are vital to successful weaning.

When cessation of nursing is necessary at an earlier age, use of a tight breast binder and application of ice bags may help decrease milk production. Restriction of the mother's fluid intake is also helpful. Small doses of estrogen for 1–2 days also may help decrease milk production at the termination of nursing.

CONTRAINDICATIONS TO BREAST-FEEDING.

Provided the mother's milk supply is ample, her diet is adequate, and she is not infected with HIV, there are no disadvantages of breast-feeding for the healthy term infant. Allergens to which the infant is sensitized can be conveyed in the milk, but the presence of such allergens is rarely a valid reason to stop breast-feeding. Rather, an attempt should be made to identify the allergen and remove it from the mother's diet.

There also are few maternal contraindications to breast-feeding. Markedly inverted nipples may be troublesome, as may fissuring or cracking of the nipples, but the latter can usually be avoided by preventing engorgement. Mastitis also may be alleviated by continued and frequent nursing on the affected breast to keep it from becoming engorged, but local heat applications and antibiotics may occasionally be necessary. Acute maternal infection may contraindicate breast-feeding if the infant does not have the same infection; otherwise, there is no need to stop nursing unless the condition of either the mother or the infant necessitates it. When the infant is unaffected, the breast may be emptied if the mother's condition permits and the milk given to the infant by bottle or cup. Mothers with septicemia, active tuberculosis, typhoid fever, breast cancer, or malaria should not breast-feed. Substance abuse and severe neuroses or psychoses also are contraindications to breast-feeding.

Formula-Feeding.

Objective nutritional studies of growing infants younger than 4–6 mo of age (e.g., rate of growth in weight and length, normality of various constituents in blood, performance in metabolic studies, body composition) differ minimally, if at all, between infants fed human milk and infants fed modern infant formulas. Although such techniques may not detect small but important variations and/or differences, these investigations attest to the ability of modern infant formulas to support normal growth and development. Thus, the mother who is unable or does not wish to nurse her infant need have no less sense of accomplishment or of affection for her infant than the nursing mother. Modern infant formulas are excellent substitutes for human milk. Moreover, the quality of attachment and mothering as well as the degree of security and affection provided the infant need not be different with formula-feeding vs. breast-feeding.

TECHNIQUE OF FORMULA-FEEDING.

The setting for formula-feeding should be similar to that for breast-feeding, with the mother or caregiver and infant in a comfortable position, unhurried, and free from distractions. The infant should be hungry, fully awake, warm, and dry. He or she should be held as though being breast-fed. The nipple holes should be of a size that allows the milk to drop slowly, and the bottle should be held so that milk, not air, channels through the nipple. Bottle propping, even with a “safe” holder, should be avoided; this not only deprives the infant of the physical contact and security of being held but, also, may be dangerous, particularly for small infants who may aspirate if unattended. Otitis media is more common in infants fed with the propped bottle.

The bottle of milk is customarily warmed to body temperature, but no harmful effects from feeding formula at room or, even, refrigerator temperature have been demonstrated. The temperature may be tested by dropping milk onto the wrist.

Eructation of air swallowed during feeding is important for avoiding regurgitation and abdominal discomfort, especially during the first 6–7 mo of life. The technique of “burping” should be the same as described for the breast-fed infant. A few infants relieve themselves best after being returned to the crib. All infants occasionally will regurgitate or “spit up” a small amount of milk after feeding, a fact that the mother should know. Spitting up seems to occur more often in the formula-fed than in the breast-fed infant.

A feeding may last from 5–25?min, depending on the age and the vigor of the infant. Because the appetite varies from one feeding to another, each bottle should contain more than the average amount taken per feeding. In no case, however, should the infant be urged to take more than desired. Excess milk should be discarded.

COMPOSITION OF INFANT FORMULAS.

The nutrient content of infant formulas marketed in the United States is

---

regulated by the Infant Formula Act, and most industrialized and many developing countries have similar regulations. All must contain minimum amounts of all nutrients known or thought to be required by infants, and increasing emphasis is being placed on not exceeding a reasonable maximum content of each. The most recent recommendations for the minimum and maximum nutrient contents of infant formulas marketed in the United States are shown in Table 41–1 . Note that the minimum recommended amount of each nutrient is greater than the amount of that nutrient in human milk and, hence, greater than the most recent Dietary Reference Intake for

that nutrient (see Table 40–1). This, most likely, reflects the perceived lower bioavailability of formula vs. human milk nutrients.

Manufacturers of infant formulas are responsible for assuring the Food and Drug Administration (FDA) that each formula contains the minimum recommended amount and no more than the maximum recommended amount of each nutrient for the intended shelf life of the formula and, also, that the formula was manufactured safely and hygienically. To this end, each batch of manufactured formula is assayed continually over the shelf life of the product. Manufacturers also are responsible for assuring the FDA that each marketed formula, as the infant's source of nutrition, supports normal growth and development for at least the first 4 mo of life. This is usually done by conducting growth studies during the first 4 mo of life in a sufficient number of infants to detect a 3?g/24?hr difference in rate of weight gain. The efficacy and safety of substituting alternative

sources of various nutrients also must be demonstrated by appropriate studies.

Most infant formulas contain a protein source, usually a mixture of bovine milk proteins but also soy protein or a variety of hydrolyzed proteins, lactose and/or other sugars, a mixture of vegetable oils, mineral salts, and vitamins. The composition of selected formulas available in the United States is shown in Table 41–2 . Most are available in powder, concentrated liquid (intended to be diluted 1:1 with water), and ready-to-feed forms. Similarities to bovine milk from which they evolved are virtually nonexistent.

NUMBER OF FEEDINGS DAILY.

The number of feedings required per day decreases throughout the 1st yr of life from eight or more shortly after birth to only three or four at 1 yr of age. The desired interval between feedings differs considerably among infants but, in general, ranges from 3–5?hr during the 1st yr of life, averaging about 4?hr. For the first 1–2 mo, feedings are taken throughout the 24?hr period; thereafter, as the quantity of milk consumed at each feeding increases and the infant adjusts his or her demand to the family pattern of daytime activities, the infant usually sleeps for longer periods at night. As the infant develops psychologically and the relationship between the parent and infant evolves, demand feeding should gradually be replaced by a feeding regimen that accommodates the needs of the infant as well as the rest of the family.

QUANTITY OF FORMULA.

The quantity of formula taken at a feeding varies among infants of the same age and within infants at different feedings. Rarely will an infant want more than 7–8?oz at a single feeding. The desire for formula (or breast milk) is somewhat less during the first 2 wk of life than during the following 5–6 mo. After 6 mo of age, formula (or breast milk) is rarely the sole source of the infant's nutrient intake. However, it remains an important source of many nutrients (e.g., calcium).

It is rarely necessary to use more than 1?qt of formula per day. By the time the infant is taking this amount, other foods should be added to the diet. Ingesting more than this volume has no advantages and may displace intake of other essential foods.

INFANT FORMULA VS. BOVINE MILK.

Although current recommendations are to avoid intake of bovine milk, particularly low fat or skimmed milk, before at least 1 yr of age, surveys suggest that a sizable percentage of infants older than 6 mo of age are fed homogenized bovine milk rather than infant formula and almost half of these are fed low-fat or skimmed milk—often on the advice of their physician.

The consequences of these practices are not known with certainty. However, infants fed bovine milk, on average, ingest roughly three times the recommended intake of protein and about 50% more sodium than the upper limit of the “safe range” of intake of this mineral but only about two thirds of the recommended intake of iron and only half of the recommended intake of linoleic acid. Ingestion of bovine milk also increases intestinal blood loss and, hence, further contributes to development of iron-deficiency anemia. The protein and sodium intakes of infants fed skimmed rather than whole bovine milk are even higher, the iron intake is equally low, and the intake of linoleic acid is very low. Ironically, while the most common reason for substituting low-fat or skimmed milk for whole milk or formula is to reduce fat and energy intakes, the total energy intake of infants fed skimmed milk is not necessarily lower than that of infants fed whole milk or formula. It appears that infants compensate for the lower energy density of low-fat or skimmed milk by taking more of it and/or increasing intake of other foods.

Whether the high protein and sodium intakes of infants fed either whole or skimmed milk are undesirable is not known with certainty. The low iron intake, clearly, is undesirable but medicinal iron supplementation should prevent development of deficiency. The low intake of linoleic acid may be more problematic. Whereas signs and/or symptoms of essential fatty acid deficiency

Isomil-SF (sucrose free) has similar composition except that glucose polymers are substituted for corn syrup and sucrose.

appear to be uncommon in infants fed either whole or skimmed milk, an exhaustive search for such symptoms has not been made. Moreover, biochemical evidence of essential fatty acid deficiency without overt signs and symptoms occurs in both younger and older infants fed formulas with a low content of linoleic acid; thus, it is likely that an exhaustive search, including biochemical indices, would reveal a reasonably high incidence of essential fatty acid deficiency. On the other hand, infants who were breast-fed or fed formulas with a high linoleic acid content earlier in life may have sufficient body stores to limit the consequences of a low intake later. However, because essential fatty acid deficiency in animals is associated with long-term deleterious effects on development, it is not wise to assume that biochemical essential fatty acid deficiency without clinically detectable symptoms is without consequences.

Resolving the issues concerning the use of bovine milk in feeding the infant is important for economic as well as health reasons. Because the cost of bovine milk is considerably less than that of infant formula, replacing formula with homogenized bovine milk obviously has important economic advantages for most families, particularly those with limited income. In addition, if the federal food assistance programs could provide homogenized bovine milk rather than formula to infants, even infants older than 6 mo of age, the program's current funds would permit expansion of benefits to many more needy infants. Clearly, this cannot be considered without further data concerning the consequences of feeding bovine milk.

FEEDING DURING THE SECOND 6 MO OF LIFE

By 6 mo of age, the infant's capacity to digest and absorb a variety of dietary components as well as to metabolize, utilize, and excrete the absorbed products of digestion is near the capacity of the adult. Moreover, teeth are beginning to erupt and the infant is more active and beginning to explore his or her surroundings. With the eruption of teeth, the role of dietary carbohydrate in development of dental caries must be considered. Consideration of the long-term effects of inadequate or excessive intakes during infancy also assumes greater importance, as does consideration of the psychosocial role of foods during development.

These considerations rather than concerns about delivery of adequate amounts of nutrients are the basis for many of the feeding practices advocated during the second 6 mo of life. Although it is clear that all nutrient needs during this period can be met with reasonable amounts of currently available infant formulas, addition of other foods after 4–6 mo of age is recommended. In contrast, the volume of milk produced by many women may not be adequate to meet all nutrient needs of the breast-fed infant beyond about 6 mo of age. This is particularly true for iron. Thus, for breast-fed infants, complementary foods are an important source of nutrients.

Complementary foods (i.e., the additional foods, including formulas, given to the breast-fed infant) or replacement foods (i.e., food other than formula given to formula-fed infants) should be introduced in a stepwise fashion to both breast-fed and formula-fed infants, beginning about the time the infant is able to sit unassisted, usually between 4–6 mo of age. Cereals, a good source of iron, should usually be the first such foods given. Vegetables and fruits are introduced next, followed shortly by meats and, finally, eggs. The order in which these foods are introduced probably is not crucial, but only one new food should be introduced at a time, and additional new foods should be spaced by at least 3–4 days to allow detection of any adverse reactions to each newly introduced food. This is particularly important if there is a

family history of food and/or other allergies.

Either home-prepared or manufactured complementary or replacement foods can be used. The latter are convenient and also likely to contain less salt. Many such products also have supplemental nutrients (e.g., iron). These also are available in different consistencies to match the infant's ability to tolerate larger size particles as he or she matures.

Prepared dinners and soups containing a meat and one or more vegetables are quite popular. However, the protein content of these products is not as high as that of strained meat. Puddings and desserts also are popular items but, aside from their milk and egg content, are poor sources of nutrients other than energy; thus, intakes of these should be limited. Moreover, intake of egg-containing products generally should be delayed, especially if there is a family history of food and/or other allergies, until after the infant has demonstrated tolerance to eggs (either a mashed hard boiled egg yolk or a commercial egg yolk preparation).

Aside from the association of bottle-feeding with dental caries after teeth have erupted, little is known about either the potential hazards or the non-nutritional role of diet during the latter half of the 1st yr of life. Thus, feeding practices during this period vary widely. Nonetheless, most recent surveys indicate that infants fed according to current practices receive adequate intakes of most nutrients.

FEEDING PROBLEMS DURING THE 1ST YR OF LIFE

Underfeeding.

Underfeeding is suggested by restlessness and crying as well as by failure to gain weight adequately. It may also result from the infant's failure to take a sufficient quantity of food even when offered. In these cases, the frequency of feedings, the mechanics of feeding, the size of the holes in the nipple, the adequacy of eructation of air, the possibility of abnormal mother-infant “bonding,” and possible systemic disease in the infant should be investigated.

The extent and duration of underfeeding determine the *clinical manifestations*. Constipation, failure to sleep, irritability, and excessive crying are to be expected. Weight gain may be slow, or there may be an actual loss of weight. In the latter case, the skin becomes dry and wrinkled, subcutaneous tissue disappears, and the infant assumes the appearance of an “old man.” Deficiencies of vitamins A, B, C, and D as well as of iron and protein may be responsible for characteristic clinical manifestations (see Chapters 42 and 44).

Treatment of underfeeding includes increasing nutrient intake, correcting deficiencies of vitamins and/or minerals, and instructing the mother in the art and practice of infant feeding. If some underlying systemic disease, child abuse/neglect, or psychologic problem is responsible, specific management of these disorders is necessary (see Chapters 35 and 36).

Overfeeding.

As a rule, postprandial discomfort from excessive intake limits the amount of food an infant voluntarily ingests, but there are exceptions. If so, regurgitation and vomiting are the most frequent symptoms. Diets that are too high in fat delay gastric emptying, cause distention and abdominal discomfort, and may cause excessive weight gain. Diets too high in carbohydrate are likely to cause undue fermentation in the intestine, resulting in distention and flatulence as well as a more rapid weight gain than desirable. Because neither breast milk nor formulas contain either excessive fat or excessive carbohydrate, such diets usually result from supplementation. This practice tends to dilute the protein, vitamin, and mineral contents of formula and, hence, should be avoided (also see Chapter 43).

Regurgitation and Vomiting.

Regurgitation refers to the return of small amounts of swallowed food during or shortly after eating. Vomiting, on the other hand, is the more complete emptying of the stomach, often occurring some time after feeding. Within limits, regurgitation is a natural occurrence, especially during the first several months of life. It can be reduced to a negligible amount by adequate eructation of swallowed air during and after eating, by gentle handling, by avoiding emotional conflicts,

and by placing the infant on the right side immediately after eating (but not for napping or sleeping). The head should not be lower than the rest of the body to avoid gastroesophageal reflux, which is common during the first 4–6 mo of life.

Vomiting is one of the most common symptoms in infancy and may be associated with a variety of disturbances—some trivial and some serious. Its cause should always be investigated.

Loose or Diarrheal Stools.

The stool of the breast-fed infant is naturally softer than that of the formula-fed infant. From about the 4th to the 6th day of life, the stools of the breast-fed infant go through a transitional stage of being loose and greenish yellow and containing mucus to the typical “milk stool.” Subsequently, the use of laxatives or the ingestion of certain foods by the mother may be temporarily responsible for a breast-fed infant's loose stools. Excessive intake of breast milk may also increase the frequency and the water content of the stool. Actual diarrhea from overfeeding, however, is unusual; thus, diarrhea should be considered infectious until proved otherwise.

Although the stools of formula-fed infants tend to be firmer than those of breast-fed infants, loose stools also may result from artificial feeding. For example, overfeeding may cause loose, frequent stools, particularly during the first 2 wk or so of life. Later, formulas that are too concentrated or too high in sugar content, especially in lactose, may produce loose, frequent stools. However, as noted earlier, this is unlikely unless sugar has been added to the formula. Many diarrheal disturbances in formula-fed infants result from contaminants that would not disturb an older child. These usually

are not serious enough to cause prolonged difficulty for the infant. The ease with which formula-fed infants acquire diarrheal disturbances and their potential seriousness are strong arguments for extreme care in preparation to assure that the formula or food is free of pathogenic bacteria.

Mild diarrheal disturbances caused by overfeeding respond quickly to temporary decrease or cessation of feeding. Withholding all solid food as well as one or several feedings and substituting boiled water or a balanced electrolyte solution are usually all that is required.

Constipation (see Chapters 5 and 287).

Constipation is practically unknown in breast-fed infants receiving an adequate amount of milk and is rare in formula-fed infants receiving an adequate intake. The consistency of the stool, not its frequency, is the basis for diagnosis. Most infants have one or more stools daily, but some occasionally have a stool of normal consistency at intervals of up to 36–48?hr.

Whenever constipation or obstipation is present from birth or shortly after birth, a rectal examination should be performed. Tight or spastic anal sphincters may occasionally be responsible for obstipation, and finger dilation is frequently corrective. Anal fissures or cracks may also cause constipation. If irritation is alleviated, healing usually occurs quickly. Aganglionic megacolon may be manifested by constipation in early infancy; the absence of stool in the rectum on digital examination suggests this possibility, but further diagnostic work-up is indicated (see Chapter 313.3).

Constipation may be caused by an insufficient amount of food or fluid. In some cases, it may result from diets that are too high in fat or protein or deficient in bulk. Simply increasing the amount of fluid or sugar in the formula may be corrective during the first few months of life. After this age, better results are obtained by adding or increasing the amounts of cereal, vegetables, and fruits. Prune juice (½ to 1?oz) may be helpful, but adding foods with some bulk is usually more effective. Enemas and suppositories should never be more than temporary measures. Milk of magnesia may be given in doses of 1–2 tsp but should be reserved for unresponsive or severe constipation.

Colic.

Colic is a symptom complex of paroxysmal abdominal pain, presumably of intestinal origin, and severe crying. It usually occurs in infants younger than 3 mo of age. The *clinical manifestations* are characteristic. The attack usually begins suddenly with a loud, more or less continuous cry. The so-called paroxysms may persist for several hours. The face may be flushed, or there may be circumoral pallor. The abdomen is usually distended and tense. The legs may be extended for short periods but are usually drawn up on the abdomen. The feet are often cold, and the hands are usually clenched. The attack may not terminate until the infant is completely exhausted. Sometimes, however, the passage of feces or flatus appears to provide relief.

Some infants seem to be particularly susceptible to colic. The *etiology* usually is not apparent, but, in some infants, the attacks appear to be associated with hunger or with swallowed air that has passed into the intestine. Overfeeding may also cause discomfort and distention; and some foods, especially those of high carbohydrate content, may be responsible for excessive intestinal fermentation. However, a change of diet rarely prevents further colic attacks.

Crying with intestinal discomfort occurs in infants with intestinal allergy, but colic is not limited to this group. Colic may mimic intestinal obstruction or peritoneal infection. Attacks commonly occur late in the afternoon or evening, suggesting that events in the household routine may be involved. Worry, fear, anger, or excitement may cause vomiting in an older child and may cause colic in an infant, but no single factor consistently accounts for colic and no treatment consistently provides satisfactory relief. Careful physical examination is important to eliminate the possibility of intussusception, strangulated hernia, or other disorders that cause abdominal pain.

Holding the infant upright or prone across the lap or on a hot water bottle or heating pad occasionally helps. Passage of flatus or fecal material spontaneously or with expulsion of a suppository or enema sometimes affords relief. Carminatives before feedings are ineffective in preventing the attacks. Sedation is occasionally indicated for a prolonged attack. If other measures fail, both the child and the parent may be sedated for a period of time. Temporary hospitalization of the infant, often with no more than a change in feeding routine and a period of rest for the mother, may help in extreme cases. Prevention of attacks should be sought by improving feeding techniques, including “burping,” providing a stable emotional environment, identifying possibly allergenic foods in the infant's or nursing mother's diet, and avoiding underfeeding or overfeeding. Colic rarely persists after 3 mo of age. Although not serious, it can be particularly disturbing for the parents as well as the infant. Thus, a supportive and sympathetic physician can be particularly helpful, even if attacks do not resolve immediately.

FEEDING DURING THE 2ND YR OF LIFE

By the end of the 1st yr of life, most infants have adapted to a schedule of 3 meals a day plus one to two snacks. Although considerable latitude in the diet of each infant should be permitted to allow for personal idiosyncrasies and family habits, the mother should be given an outline of the basic daily dietary needs. Equally important, she should be aware of what to expect in terms of eating behavior as the child matures.

Reduced Food Intake.

Toward the end of the 1st yr of life, the rate of growth decreases and the child's intake, accordingly, also decreases or fails to increase as rapidly as it did during the 1st yr of life. It is not unusual for the child to have temporary periods of not being interested in certain foods or, indeed, in any food. Failure to expect and recognize these changes in eating behavior often results in attempts to force feed. The child naturally rebels and feeding problems ensue. Because preventing problems is more effective than correcting them, the changing pattern of food habits during the 2nd yr of life should be

explained to the mother before it is apparent. She should be reassured that the lack of interest in food is probably temporary and that attempts to force feed not only are futile but also likely to result in more severe feeding problems.

Self-Selection of Diet.

Children's strong likes or dislikes of particular foods become apparent after about 1 yr of age and, if possible and practicable, should be respected. For example, the virtues of some foods (e.g., spinach) that are nonessential have been overemphasized; certainly, conflicts about such foods should not be allowed to occur. Often a food that is refused when it is first offered will be accepted when it is offered again a few days or weeks later. On the other hand, if basic staples such as milk and cereal are consistently rejected, food allergy should be considered. If this is not a problem, alternative forms of these basic staples (e.g., cheese, yogurt, breads) should be offered.

Children tend to select diets that, over several days, are well balanced. Thus, the child may be permitted a wide choice of foods, as long as he or she eats adequately over the longer period. Normally, the child determines the quantity of a given food as well as an entire meal that will be eaten. At this age, eating habits, particularly food likes and dislikes, also may be influenced by older children in the family. Thus, because eating patterns and habits developed in the first 2 yr of life usually persist for several years, such influences should be monitored closely.

Self-Feeding by Infants.

Infants should be permitted to participate in feeding themselves as soon as they seem physically able to do so, usually long before 1 yr of age. By approximately 6 mo of age, infants can hold a bottle and, within another 2–3 mo, can hold a cup. Zwieback, graham crackers, or other hand-held foods can be introduced by the age of 7–8 mo. The infant may be allowed to use a spoon as soon as it can be held and directed to the mouth, usually between 10–12 mo of age. Mothers often inhibit this important learning process because of its messiness, but it is an important aspect of the infant's overall development and should be encouraged. By the end of the 2nd yr of life, infants should be largely responsible for feeding themselves. However, because the risk of aspiration is reasonably high until approximately 4 yr of age, infants younger than this should not be given foods that are easily aspirated (e.g., grapes, nuts, chunks of cheese and meat) unless a responsible adult is present.

Basic Daily Diet.

Parents should be given a basic daily diet plan for the child from which the family menu can be prepared. Daily selection from each of the food groups (grains, fruits, vegetables, meats, and dairy products) provides a balanced diet with sufficient macronutrients and micronutrients. The quantity of intake after the basic requirements have been met can usually be determined by the healthy growing child. The child's dietary history is essential for evaluating the nutrient intake but, unless an accurate dietary diary is kept for several days, such histories are often unreliable. Correcting the diet can be much more effective if reliable information is available.

The older child should learn the content of a basic well-balanced diet and its importance to proper growth and good health. However, this information should never be presented as a threat to enforce rigid feeding practices.

Eating Habits.

Eating habits formed in the 1st and 2nd yr of life distinctly affect those of the subsequent years. Feeding difficulties frequently result from excessive parental insistence on eating and subsequent anxiety of the parents and the child if the child fails to heed this insistence. The child's negative reactions often result from undue mealtime stress, the correction of which requires improvement in parent-child relations. Other factors that disturb eating are too much confusion at mealtime, insufficient time for eating on the part of either the adults and older children of the household or the child, food dislikes of other members of the family, and poorly prepared, unattractively served food. Mealtimes should be happy, with conversation concerning subjects of interest to the entire family. A comfortable chair of proper height with a footrest is important for the smaller child's ease at the table.

The child's appetite should be respected; if his or her desire for food is below average at times, there should be no persuasion to eat more. Adults should realize that eating habits are taught better by example than by formal explanation.

Snacks Between Meals.

During the 2nd yr of life and for several years thereafter, orange juice or other fruit juice or fruit, together with a cracker, may be given at either or both of the between-meal periods. Snacks served in childcare facilities should be similarly nutritious.

Vegetarian Diets.

All-vegetable diets can supply all necessary nutrients but, to do so, the vegetables and grains comprising the diet must be selected from different classes. Vegetables are high in fiber content, vitamins, and minerals. Because of the higher fiber intake, vegetarians usually have faster gastrointestinal transit time, bulkier stools, and lower serum cholesterol levels; as adults, they may be less likely to develop diverticulitis and appendicitis than meat eaters. Vegetarians who consume eggs (ovovegetarians) and milk (lactovegetarians) obviously have more choices for constructing a well-balanced diet than those who consume neither (vegans). Vegans may develop vitamin B_{12} deficiency and, because of high fiber intake, may develop trace mineral deficiencies. Nursing vegan mothers must be given supplemental vitamin B_{12} to prevent methylmalonic acidemia in their infants. There also is some concern that vegetarian infants may not grow as rapidly as omnivores during the first 2 yr of life.

FEEDING DURING LATER CHILDHOOD

After 2 yr of age, a child's diet should not differ from that of the rest of the family. All

known required nutrients are supplied by a varied diet selected according to the Food Pyramid Guidelines (Fig. 41–1). These guidelines with emphasis on grains, fruits, and vegetables are consistent with the recommendations of the National Cholesterol Education Program, including restriction of dietary fat to approximately 30% of the total daily energy intake, saturated fatty acids to less than 10% of energy, and cholesterol to no more than 100?mg/1,000?kcal. Polyunsaturated fatty acids should supply 7–8% of energy and monounsaturated fatty acids should supply 12–13%. This diet, the American Heart Association Step One Diet, is recommended to decrease atherosclerotic heart disease in adulthood and may also be effective in limiting the development of obesity. There is some argument about the importance of such a diet before adolescence, except for those children with a strong family history of atherosclerotic heart disease. However, such diets support normal growth of children as young as 1 yr of age and implementing it after about 2 yr of age may be easier than doing so at adolescence.

Although initially developed for older children and adults, the Food Guide Pyramid has recently been adapted for 2–6 yr old children. This pyramid is shown in Figure 41–1 . The suggested number of servings per day from the various food groups as well as the suggested serving sizes for each group are shown in Table 41–3 . These are targeted to meet the recommended daily allowances (RDAs) for energy, protein, vitamins, and minerals established by the Food and Nutritional Board, National Academy of Sciences, in 1989. The more recent Dietary Reference Intakes (see Table 40–1) for some nutrients differ from these but, because most are lower, are not likely to have a major impact on the number of servings needed daily from each food group.

The number of servings from each food group needed for well-balanced 1,600?kcal/24?hr, 2,200?kcal/24?hr, and 2,800?kcal/24?hr diets are shown in Table 41–3 . The 1,600?kcal/24?hr diet is appropriate for the moderately active 4–6 yr old child.

Figure 41-1 Food guide pyramid for 2–6 yr old children. (From U.S. Department of Agriculture/ USDHHS.)

However, this energy intake may be excessive for less active children, and it may not be sufficient for the very active child. The goal should be to support normal rates of weight gain without excessive fat deposition. Most children, if not forced to eat more, will adjust intake to achieve this goal.

The 2,200?kcal/24?hr diet is appropriate for most moderately active 6–10 yr old children. Older, very active children of this age group may require somewhat more energy, and younger, less active children may need less. Active teenage boys may require at least 2,800?kcal/24?hr, sometimes more. In general, the energy needs of girls are somewhat less than those of boys.

Note that the increasing requirements with age can be met by increasing the number of servings of each food group rather than the size of the servings. For example, the number of servings suggested for the 2,800?kcal/24?hr diet is the same as suggested for active adults, some of whom need less and some of whom need more than 2,800?kcal/24?hr.

Although these guidelines are useful and can be used to design an appropriate diet for all children older than 2 yr of age, the variation in energy needs among children of the same age is considerable. The level of activity is a major determinant of the amount of energy needed, but this is not the only factor. Variations in energy expenditure among seemingly similar groups of children can vary by as much as 15–20%. Thus, even those children whose diets are based on the Food Guide Pyramid must be observed closely to ensure that growth is adequate but not excessive.

As children become older and more independent, an increasing number of meals are eaten away from home, often at “fast food”

TABLE 41-3 -- **Servings Needed to Provide Differing Energy Intakes**

Food Group	Servings Needed for Daily Energy Intake of:		
	1600?kcal	*2200?kcal*	*2800?kcal*
Bread	6	9	11
Fruit	2	3	4
Vegetable	3	4	5
Meat	5?oz	6?oz	7?oz
Milk	2–3	2–3	2–3
Total fat (g)	53	73	93
Added sugar (tsp)	6	12	18

restaurants where adherence to the Food Guide Pyramid principles is difficult, if not impossible. An obvious solution is to limit such occasions to once or, at most, twice per week. However, this is often resisted by the child. Moreover, with the increasing number of mothers in the work force, many family meals are either eaten at the same establishment or purchased there for consumption at home. Perhaps the most a pediatrician or nutritionist can hope for is that the parents understand the importance of a well-balanced diet and how best to achieve this without undue hardship for themselves or their children. **REFERENCES**

Chapter 42 - Food Insecurity, Hunger, and Undernutrition

William C. Heird

Food insecurity, hunger, and undernutrition are often viewed as a continuum, with food insecurity resulting in hunger and, ultimately, if sufficiently severe and/or of sufficient duration, in undernutrition. According to this view, food insecurity indicates inadequate access to food for whatever reason, hunger is the

immediate physiologic manifestation of inadequate intake, and undernutrition describes the biochemical and/or physical consequences of chronically or acutely inadequate intake. However, it is now recognized that this view is incomplete. Although the continuum from food insecurity to hunger and, ultimately, to undernutrition is often true, particularly in developing countries, all food-insecure children do not experience hunger and all undernourished children do not experience food insecurity before becoming undernourished. Each condition, not only undernutrition, has consequences for the individual, the family, and society. Thus, viewing these conditions as an inevitable continuum distorts estimates of the prevalence, causes, and consequences of each condition. It also may lead to inappropriate policy responses as well as to inappropriate treatment and/or failure to recognize and, it is hoped, remedy conditions other than overt undernutrition. It is important to understand the nature of each of these problems and their relationships to each other.

FOOD INSECURITY

Food insecurity can be defined in a number of ways. The broadest definition is “limited or uncertain availability of nutritionally adequate and safe foods in socially acceptable form and by socially acceptable ways.” This definition encompasses concepts of the certainty of both short-term and long-term availability of and access to food; concerns about the sufficiency, nutritional quality, and safety of food; and the cultural and social acceptability of accessible food and the means by which this food is acquired.

The concept of food security differs depending on whether it is viewed from a global, a national, a household, or an individual perspective. Globally, food security concerns the overall availability of sufficient food to feed the population of the world. Food security from a national perspective also concerns availability of food. However, the issue is not whether enough food is produced globally to feed the population of the world but whether enough food is produced and/or imported to feed the population of the country. From a household perspective, food security concerns availability of and access to adequate food from household production, local purchase, or some combination of production and purchase. Food security, from an individual perspective, concerns the amount and quality of food available for consumption by the individual. This is a function of the availability of and access to food by the household and the distribution of food within the household.

In some developing countries, food insecurity results from the lack of sufficient food to feed the entire population of the country. This often is a result of war, famine, or some other disaster, but it also can result from a lack of resources to assure adequate production, importation, and/or distribution of food. However, the consequences of food insecurity in such countries as well as in food-rich countries is experienced primarily at the household and individual levels. At the household level, these consequences usually result from a managed process in which inadequate means to obtain food, either because it is not available or because resources are limited, leads to anxiety about the supply of food and this anxiety, in turn, results in a variety of coping tactics (e.g., stretching food money). If these coping tactics are not successful, intake eventually is restricted, resulting not only in nutritional consequences but also emotional consequences for the household as well as individual members of the household. The anxiety over the availability of food usually leads, first, to lower intakes of food or intake of less nutritionally adequate food by women, then a lower quantity and/or quality of the overall household food supply, and, eventually, to a lower quantity and/or quality of children's intakes.

Food insecurity in both developing and developed countries is a form of deprivation, either deprivation per se or the feeling of deprivation. The subjective experience of food insecurity at the individual level is central. Thus, the relevant assessment of food security is that perceived by the household or individual rather than what is decided by researchers or policymakers; if individuals do not believe that food is secure, food insecurity is a problem. Moreover, this problem is a multilevel and multidimensional one, with implications for how food security is assessed and for efforts to improve food security.

Measurement.

Estimates of global and national levels of food insecurity are made by estimating the number of people whose intake does not provide enough energy to meet basic energy requirements. This is often equated to the number of undernourished individuals. However, this definition reflects only national food availability, not an individual's ability to access food. Thus, while the number of undernourished individuals is a direct measure of food security at the global or national level, it does not reflect access to and utilization of food by individuals. Hence, it is not a measure of food security at the household or individual level.

How to measure household and individual food security is not clear. Certainly, food insecurity affects intake and, ultimately, nutritional status. Furthermore, measuring intakes of individuals either directly or indirectly by the number of undernourished individuals assesses some aspects of food security (e.g., energy adequacy). However, it does not assess the cognitive and affective components of the uncertainty of food security, nor does it assess the unacceptability and unsustainability of food insecurity. For example, food insecurity exists if there is anxiety that food, although sufficient at the present time, may soon become inadequate. Not only does growth status, per se, not assess many components of food security, it is also an indirect outcome that depends on health and care as well as intake. Thus, in assessing food insecurity, it is important to measure not only the availability and access to food but also the experience of food insecurity, (i.e., how individuals feel about the security of their food supply).

A variety of questionnaires have been used to assess food insecurity in developed countries. These include questions concerning availability of food, concern about availability of food, and whether lack of availability was associated with hunger. These have reliability coefficients ranging from about 0.75 for all households to about 0.8 for households with children. The scores, as expected, are related to income, indicating that food insecurity is more prevalent among families with incomes close to the poverty level. Scores on these questionnaires defining food insecurity also are in agreement with data concerning weekly food expenditures.

Prevalence.

Food insecurity is much more prevalent in developing countries than in developed countries. Current estimates of the prevalence of food insecurity in developing countries, based on estimates of undernutrition, indicate that about 18% of all individuals in developing countries are undernourished. Estimates of prevalence vary throughout the world, ranging from about 33% of all individuals in most parts of Africa and about 17% of those in Asia and the Pacific to much lower percentages in most other parts of the world. Because these estimates are based on the number of undernourished individuals, they obviously include only those individuals whose intakes are sufficiently low to result in undernutrition. Hence, the prevalence of food insecurity, as broadly defined, is likely to be considerably greater. On the other hand, these estimates equate food insecurity with undernutrition that results from some combination of inadequate nutrient intake and inadequate care.

Based on questionnaires assessing food security, about 10% of all households in the United States were food insecure in 1999. The prevalence of food insecurity without hunger was 7% of all households, and the prevalence with hunger was 3% of all households. This prevalence equates to 31 million persons in

food insecure households. The prevalence of food insecurity is higher in central city and rural areas than in suburban areas. It also is much higher among black and Hispanic households as well as households headed by single women. Estimates of the prevalence of food insecurity without hunger in these households range from 20–30%.

A typical food-insecure household in the United States is not necessarily one in which there is no working member. Rather, at least one member of the household is likely to be employed, albeit in jobs that pay barely enough to enable the family to "get by." In such households, food becomes expendable when the available resources are needed to meet expenses such as rent and/or utilities, transportation in order to continue employment, medical care, and/or other basic needs.

Consequences.

Biologic consequences of food insecurity are secondary to inadequate intake. However, the social and behavioral consequences can be secondary to the aspects of food insecurity experienced at the household or individual level as well as the biologic consequences. For example, food insecurity among women of sufficient severity to result in nutrient insufficiency and, hence, undernutrition leads to a higher prevalence of low birthweight infants and may affect breast milk production adversely. These effects, in turn, result in impaired cognitive and neurologic development of the offspring, lower educational achievement, and, hence, a lower likelihood of finding productive work in adulthood. The more severely affected individuals may also have a poor capacity to work, further decreasing their ability to be food secure. This vicious cycle may continue from one generation to the other and perpetuate both the biologic consequences of food insecurity and consequences secondary to the behavioral responses to food insecurity.

Even food insecurity that does not result in overt undernutrition may be associated with a low intake of foods such as fresh fruits and vegetables and, hence, a low intake of several essential nutrients (e.g., vitamins A, E, C, and B_6 as well as magnesium, potassium, and/or fiber [see Table 44–1]). Some studies suggest that women from food-insecure households are more likely to have higher body mass indices and to be obese than women from food-secure households. However, this is not a linear relationship; neither the incidence of obesity nor the body mass indices of women from households with more severe problems (i.e., childhood hunger) differ from those of women from food-secure households.

Clinical Manifestations and Treatment.

Unless food insecurity is of sufficient severity to result in food insufficiency and undernutrition, it is not associated with obvious signs and/or symptoms. Thus, it is not likely to be recognized by physicians and other health care workers. Furthermore, even if food insecurity is suspected, a physician can do little except offer understanding and support. Nonetheless, considering the apparent prevalence of food insecurity among poor families, physicians caring for these families are likely to encounter children from food-insecure households. If food insecurity is suspected, further inquiries should be made, both to confirm that the family is food insecure and to assess the severity of the insecurity. These assessments should include information about the child's diet.

A food frequency interview, which provides such information as the number of servings per week of each major food group (see Fig. 41–1), is a reasonable place to start. Should this suggest an imbalanced diet (e.g., low intake of any of the food groups), the next step is to have the mother complete a 3–5 day food diary. If obtained and analyzed appropriately, this can provide quantitative information about dietary intake, including estimates of the intake of specific nutrients. This can be done by the physician, a nutritionist, or a dietitian.

If an intake of any nutrient is less than the Dietary Reference Intake, appropriate dietary advice should be given and/or appropriate supplements prescribed. Many food insecure children are likely to benefit from a multivitamin supplement, but fewer are likely to require macronutrient supplements. If no specific deficiencies are identified, the family may benefit from nutritional counseling, including not only the desired number of servings from each food group but also the most economical source of these foods. The physician should also ensure that the family is aware of the federal, state, and/or local resources available for assistance.

HUNGER

Hunger is the uneasy sensation that results from lack of food. It is a potential, although not inevitable, consequence of food insecurity. However, the concept of hunger differs among individuals, even individuals with similar dietary intakes. Thus, it is even more difficult to define and assess than is food insecurity.

A questionnaire developed by the Community Childhood Hunger Identification Project reliably categorize families as "hungry," "at risk for hunger," or "not hungry" on the basis of answers to eight standardized questions about child and family experiences of food insecurity or insufficiency attributable to constrained resources. Using this measure of food insufficiency as the principal indicator of hunger, this project estimates that 8% of poor children younger than age 12 yr in the United States experience hunger from time to time and that an additional 21% are "at risk for hunger." However, hunger is even more prevalent in children from families with the lowest incomes. Among these families, as many as 21% of children may be hungry and an additional 50% may be "at risk for hunger." This suggests that almost three fourths of the poorest children in the United States may experience food insecurity or insufficiency. It also suggests that hunger is an issue for many of these children and is a serious problem for some. On the other hand, all of these children obviously do not experience food insecurity of sufficient severity to result in undernutrition.

Psychosocial problems, like food insecurity and hunger, also are common among children from low-income families. Estimates of the prevalence of such problems in these children range from 10–30%; estimates of the prevalence of such problems among children from more advantaged families are considerably lower. There also is a relationship between the prevalence of psychosocial problems among low-income families and hunger. In one study, 29% of "hungry" children, 15% of "at risk for hunger" children, and 14% of "not hungry" children were receiving special education services. In the same study, 21% of "hungry" children, 12% of children "at risk for hunger," but only 5% of "not hungry" children had a history of mental health counseling. "Hungry" children also were more likely to have a history of academic failure as well as to demonstrate higher levels of anxious, irritable, aggressive, and oppositional behaviors than their low income, but "not hungry," peers. These findings are similar to the behavioral findings of more severe, chronic undernutrition in developing countries.

The above conclusions are based on correlations that do not necessarily prove a

cause-and-effect relationship. Although it is possible that hunger causes the types of behavior problems documented, it also is possible that hunger is a correlate of still another variable rather than the direct cause of the problems. For example, parents who are emotionally drained by chronic illness or the constant struggle to make ends meet are less likely to be able to cope with planning for nutritious and economic food purchases. In other words, hunger may be more prevalent in such families but the other problems of the families may play an equal or a larger role in determining the children's functioning.

Clinical Manifestations and Treatment.

The nature of hunger makes it difficult to recognize. Moreover, because the perception of hunger varies considerably both among individuals, even

individuals ingesting the same diet, and within the same individual from day to day, asking the child if he or she is ever hungry or questioning the parent may not be helpful.

If hunger is suspected, use of the parental questionnaire developed by the Community Childhood Hunger Identification Project or a similar questionnaire may be useful. Children identified by this instrument as "hungry" or "at risk for hunger" should be evaluated for the possibility of nutrient deficiencies. If present, these should be treated with either supplements or dietary advice. Their parents should be referred to the appropriate agency for assistance.

In some cases, a change in meal patterns without an increase in overall intake may be useful. For example, if entire meals are missed to stretch the available food money, it might help to decrease the quantity of other meals to provide an appropriate number of meals per day.

UNDERNUTRITION

For decades, investigators have searched unsuccessfully for a single cause or a specific set of causes of undernutrition and the appropriate intervention strategies to correct that cause or set of causes. For example, attention has shifted from inadequate protein to inadequate energy to inadequate micronutrients with accompanying shifts of focus concerning appropriate intervention strategies. Problems and causes of undernutrition that are being debated currently include growth faltering, low birthweight, maternal undernutrition, deficiencies of specific nutrients (e.g., iodine, vitamin A, iron, and zinc), diarrhea, HIV infection and other infectious diseases, inadequate infant and child feeding practices, female time constraints, limited household income, limited agricultural production, food insecurity, environmental degradation, and urbanization. A wide array of solutions to these problems also are debated. These include growth monitoring, promotion of more optimal breast-feeding and complementary feeding practices, nutrition education, oral rehydration programs, child spacing, food fortification, supplementation of specific or multiple nutrients (e.g., vitamin A, iron, and/or zinc), income generation, food aid, home gardening, and agricultural intensification. To a great extent, this shifting illustrates the poor understanding of many aspects of the major worldwide problem of undernutrition.

The problem of undernutrition is multifaceted, and solving it at a national level requires understanding, trust, and cooperation among diverse governmental agencies accustomed to dealing solely with health, agriculture, education, or finance issues. The frequent shifting of focus has not generated a coherent and understandable approach to the problem but, rather, has helped create the perception among many national policy makers and planners that the nutrition problem is "too complicated." This, in turn, has delayed coordination of efforts across international and governmental agencies and, equally important, has not generated a consensus within the nutrition community about priority problems and the actions and strategies needed to solve them.

In response to this situation, the United Nations Children Fund (UNICEF) has developed and is promoting an inclusive conceptual framework for organizing scientific knowledge and experience concerning undernutrition (or malnutrition), fostering a common understanding and developing coherent strategies for addressing the problem. A key feature of this framework is the recognition that undernutrition, or malnutrition, is a biologic manifestation of the combined effects of inadequate dietary intake and disease, both of which are closely related to social and economic development. Thus, malnutrition cannot be viewed as distinct from other development problems but, rather, as a reflection of these other problems.

Another feature of this framework is that the assumptions underlying various approaches to malnutrition are stated explicitly so that they can be questioned and debated. This is in contrast to the usual tendency to assume implicitly that malnutrition is due solely to a specific cause (e.g., lack of food, inadequate health care, limited education, poor breast-feeding practices, inadequate agricultural production). Another key feature of the UNICEF framework is that the relative importance of the underlying causes of malnutrition (food, health care) must be recognized widely across households, communities, and countries. This implies that universal causes and solutions do not exist and that constraints in providing adequate food and health care must be assessed and acted on in each setting. A highly decentralized approach to assessment, analysis, and action is required rather than imposed national or global solutions.

Measurement.

The traditional approach to nutritional assessment measures only the physical manifestations of the problem (i.e., clinical, anthropometric, and biochemical indicators) and, perhaps, some of the immediate causes related to dietary intake. These indicators may be adequate for estimating the magnitude of the problem, but additional methods and approaches are needed to assess the broader nutrition situation. These approaches include consideration not only of dietary intake but also of health care and control of resources at household, community, and national levels.

Despite the need for additional methods and approaches, a number of anthropometric indices have been used successfully for many years to estimate the prevalence of undernutrition among preschool-aged children. These include height for age, weight for age, and weight for height. The first is an index of the cumulative effects of undernutrition during the life of the child, the second reflects the combined

effects of both recent and longer-term levels of nutrition, and the last reflects recent nutritional experiences. Values below 80–90% of expected are considered abnormally low.

These indices are reasonably sensitive indicators of the immediate and underlying general causes of undernutrition, but they are not specific for any particular cause. They do not reveal the relative importance of dietary intake, infectious diseases, food insecurity, inadequate health/environmental services, low birthweight, suboptimal childcare practices, income constraints, or disparities in control of resources. These factors are part of the assessment of the overall nutrition situation and are distinct from the biochemical and/or anthropometric indicators that merely reflect the severity and extent of the problem, its distribution across geographic and social groups, and trends over time.

Prevalence.

In 2000, 26.7% of preschoolers in the developing world were estimated to be underweight, as reflected by a low weight for age, and 32.5% were estimated to be stunted based on a low height for age. These estimates are about 11% and about 15% lower, respectively, than estimates in 1980, suggesting considerable improvement, at least in some regions, over these 2 decades. However, the population of the developing world increased during this time; thus, the total number of underweight and stunted children has not changed dramatically since 1980.

Data from the United States and other developed countries indicate that the prevalence of undernutrition as manifested by a low weight for age or height for age is very low. Data from the National Health and Nutrition Examination Survey (NHANES) III (1988–1991) indicate that the prevalence of low height for age (below the 5th percentile) was 4–5% among children from 2?mo to 11 yr of age, about the same prevalence noted by NHANES I (1971–1974) 2 decades earlier. The NHANES III data also show that populations with a high prevalence of poverty do not have a higher prevalence of undernutrition than the general population, emphasizing the importance not only of adequate intake but also of adequate care as defined in the United Nations International Child's Emergency Fund (UNICEF) framework.

In contrast to the low prevalence of undernutrition among the general population of children in the United States and other developed countries, the prevalence among hospitalized children is often as high as in developing countries.

Consequences.

The cumulative evidence suggests that undernutrition has pervasive effects on immediate health and survival as well as on subsequent performance. These include not only acute effects on morbidity and mortality but also longer-term effects on cognitive and social development, physical work capacity, productivity, and economic growth. The magnitude of both the acute and longer-term effects are considerable. Prospective studies suggest that severely underweight children (<60% of reference weight for age) have more than an eight-fold greater risk for mortality than normally nourished children, that moderately underweight children (60–69% of reference weight for age) have a four- to five-fold greater risk, and that even mildly underweight children (70–79% of reference weight for age) have a two- to three-fold greater risk. The high prevalence of mortality in those with mild and moderate undernutrition suggests that more than half of child deaths may be caused directly or indirectly by undernutrition. Moreover, 83% of these deaths result from mild to moderate forms of undernutrition. A major factor is the potentiation of infectious diseases by undernutrition.

Survivors of childhood undernutrition frequently have deficits in height and weight that persist beyond adolescence into adulthood. These deficits are often accompanied by deficits in frame size as well as muscle circumference and strength. The implications of these deficits with respect to the work capacity of both men and women and to women's reproductive performance are obvious. Survivors of childhood malnutrition also have deficits in cognitive function and school performance relative to normally nourished children from the same environment. Mean deficits in scores on standard tests of cognition range from 5–15 points. The fact that severely undernourished children, as assessed by low length-for-age, have greater deficits in cognitive performance than children with mild or moderate undernutrition strongly suggests that the intellectual deficits are related to the severity of undernutrition.

The extent to which intellectual deficits can be decreased by dietary intervention alone is not clear. However, these deficits can be decreased by a combination of dietary and behavioral interventions coupled with improvements in the overall quality of the home and/or school environment. Such interventions appear to be much more effective if instituted in early life.

Prevention.

Food insecurity and undernutrition are the behavioral or biologic manifestations of problems that are rooted in the social world from the level of individuals and households to the community, national, and international levels. Thus, a wide range of scientific disciplines must be drawn on to maximize the possibility of effective and sustainable solutions. For example, an intervention as simple as supplementing the population with vitamin A requires an understanding of the behavior of households, communities, clinical workers, program managers, and policymakers. Scientific approaches for addressing such problems must include, but go well beyond, the biologic sciences that have formed the core of the discipline of nutrition.

The evolution of thought concerning food security and undernutrition in developed and developing countries has some commonalities with significant policy implications. The major commonality is the recognition that the causes of these problems, while strongly related globally to poverty, are highly contextual and, hence, easily misunderstood. In most developed countries, for example, not all food-insecure individuals live in poverty and all those living in poverty are not food insecure. Similarly, in developing countries, child malnutrition secondary to suboptimal health conditions or caring practices is common even among households with ample food resources. Thus, food insecurity and undernutrition arise from a variety of social, economic, and ecologic situations that vary from time to time and from place to place. Therefore, the coping strategies and behaviors of individuals

and households as well as communities and nations are highly responsive to a variety of microcontextual factors. Moreover, these coping strategies and behaviors are strongly influenced by the ways in which the food insecure and undernourished experience reality. For example, the risk avoidance and risk management strategies of poor households often discourage their adopting new crop varieties or making other changes in their livelihood strategy despite the fact that such changes appear desirable and rational to outsiders.

Many policies and programs have been ineffective because they do not adequately assess, anticipate, and embrace the coping strategies and likely responses of the population. Some programs that do so have been initiated in communities throughout the developing world and are currently being evaluated. It is hoped that the results of these efforts will suggest strategies to improve the total nutrition situation and reduce high prevalence of childhood undernutrition.

Clinical Manifestations and Treatment.

Undernutrition ranges from a lower than desired intake of one or more nutrients with either no symptoms or only vague symptoms to severe malnutrition. The approach to treating mild undernutrition is the same as that suggested for food insecurity of sufficient severity to result in low intake of specific nutrients. Treatment of vitamin deficiencies is discussed in Chapter 44 , and treatment of the most severe form of undernutrition is discussed in the following section of this chapter.

PROTEIN/ENERGY MALNUTRITION

Deficiency of a single nutrient is an example of undernutrition or malnutrition. Usually, however, there is deficiency of several nutrients. Protein/energy malnutrition (PEM), for example, is manifested primarily by inadequate dietary intakes of protein and energy, either because the dietary intakes of these two nutrients are less than required for normal growth or because the needs for growth are greater than can be supplied by what, otherwise, would be adequate intakes for growth. However, PEM is almost always accompanied by deficiencies of other nutrients.

The terms *primary* and *secondary* malnutrition refer, respectively, to malnutrition resulting from inadequate food intake and malnutrition resulting from increased nutrient needs, decreased nutrient absorption, and/or increased nutrient losses. Although both primary and secondary malnutrition occur in developing as well as developed countries, primary malnutrition accounts for the major percentage of malnourished children in developing countries, whereas secondary malnutrition accounts for a higher percentage in developed countries.

PEM, whether primary or secondary, is a spectrum ranging from mild undernutrition resulting in some decrease in length and/or weight for age through severe forms of undernutrition resulting in more marked deficits in weight and length for age as well as wasting (i.e., a low weight for length). Historically, the most severe forms of PEM, marasmus, and kwashiorkor, were considered distinct disorders. Marasmus was thought to result primarily from inadequate energy intake, whereas kwashiorkor was thought to result primarily from inadequate protein intake. Currently, a third disorder, marasmic kwashiorkor, which has features of both disorders, also is recognized. The three conditions have distinct clinical and metabolic features, but they also have a number of overlapping features. For example, a low plasma albumin concentration, often thought to be a manifestation of kwashiorkor, is common in children with both clinical marasmus and clinical kwashiorkor. In recognition of the overlapping features of these two clinically distinct conditions, the terms currently preferred are *edematous* (kwashiorkor) and *nonedematous* (marasmus) PEM. The underlying causes of this

spectrum of conditions are quite similar. Among these are social and economic factors such as poverty and ignorance, social factors such as food taboos, biologic factors such as maternal malnutrition and inadequate intakes of breast milk and other foods, as well as environmental factors such as overcrowded and unsanitary living conditions.

Clinical Manifestations.

In *nonedematous PEM* (marasmus) initially there is failure to gain weight and irritability, followed by weight loss and listlessness until emaciation results. The skin loses turgor and becomes wrinkled and loose as subcutaneous fat disappears. Loss of fat from the sucking pads of the cheeks may occur late, and the infant's face may retain a relatively normal appearance, compared with the rest of the body, eventually becoming shrunken and wizened. The abdomen may be distended or flat with the intestinal pattern readily visible. There is muscle atrophy and resultant hypotonia. The temperature is usually subnormal and the pulse slow. Infants are usually constipated but may develop a starvation diarrhea with frequent small stools containing mucus.

Edematous PEM (kwashiorkor) may initially present as vague manifestations that include lethargy, apathy, or irritability. When well advanced, there is inadequate growth, lack of stamina, loss of muscle tissue, increased susceptibility to infections, vomiting, diarrhea, anorexia, flabby subcutaneous tissues, and edema (Fig. 42–1). The edema usually develops early and may mask the failure to gain weight, but the liver may enlarge early or late. The edema is often present in internal organs before it is recognized in the face and limbs. Dermatitis is common, with darkening of the skin in irritated areas but not in areas exposed to sunlight, in contrast to pellagra (see Chapter 44). Depigmentation may occur after desquamation in these areas, or it may be generalized. The

Figure 42-1 *A,* Kwashiorkor in a 2 yr old boy. Note the generalized edema, the typical skin lesions, and the state of prostration. *B,* Close-up of the same child showing the hair changes and psychic alterations (apathy and misery); the edema of the face and the skin lesions can be seen more clearly. (Photographs made available by the Institute of Nutrition of Central America and Panama, Guatemala, courtesy of Moises Behar, MD.)

hair is sparse and thin and, in dark-haired children, may become streaky red or gray. The texture is coarse in chronic disease. Eventually, there is stupor, coma, and death.

Pathophysiology.

Many of the manifestations of PEM represent adaptive responses to inadequate energy and/or protein intakes. In the face of inadequate intakes, activity and energy expenditure decrease. However, despite this adaptive response, fat stores are mobilized to meet the ongoing, albeit lower, energy requirement. Once these stores are depleted, protein catabolism must provide the ongoing substrates for maintaining basal metabolism.

Why some children develop edematous PEM and others develop nonedematous PEM is unknown. Although no specific factor has been identified, a number have been suggested. One concerns the variability among infants in nutrient requirements and in body composition at the time the dietary deficit is incurred. In addition, it has been proposed that giving excess carbohydrate to a child with clinical marasmus reverses the adaptive responses to low protein intake, resulting in mobilization of body protein stores. Eventually, albumin synthesis decreases, resulting in hypoalbuminemia with edema. Fatty liver also develops secondary, perhaps, to lipogenesis from the excess carbohydrate. Aflatoxin poisoning as a cause of edematous PEM also has been proposed. Finally, free radical damage has been proposed as an important factor in development of clinical kwashiorkor or edematous PEM. This concept is supported by low plasma concentrations of methionine, a dietary precursor of cysteine, one of the amino acids needed for synthesis of the major antioxidant factor, glutathione. This possibility also is supported by lower rates of glutathione synthesis in children with edematous vs. nonedematous PEM.

Treatment.

The usual approach to treatment of PEM includes three phases. The first relatively brief phase (24–48?hr) is a stabilization phase. During this phase, dehydration, if present, is corrected and antibiotic therapy is initiated to control infection. Because of the difficulty of estimating hydration, oral rehydration therapy is preferred. If intravenous therapy is necessary, estimates of dehydration should be reconsidered frequently, particularly during the first 24?hr of therapy.

The second phase includes continued antibiotic therapy with appropriate changes if the initial combination was not effective and introduction of a diet providing maintenance requirements of energy and protein (~75?cal/kg and ~1?g/kg/24?hr of protein) along with adequate electrolytes, trace minerals, and vitamins. This phase usually lasts for an additional week to 10 days. If the infant is unable to take the feedings from a cup or bottle, administration of feedings by nasogastric tube rather than by the parenteral route is preferred.

By the end of the second phase, any edema that was present has usually been mobilized, infections are under control, the child is becoming more interested in his or her surroundings, and his or her appetite is returning. The child is then ready for the final phase of treatment, which consists primarily of feeding. He or she should be switched gradually to a recovery diet providing up to 150?kcal/kg/24?hr and 4?g/kg/24?hr of protein. After adjustment to this diet, the child can be fed ad libitum. Once ad libitum feedings are allowed, intakes of both energy and protein can be substantial.

In developing countries, this phase is often carried out at home. However, continued hospitalization is much more effective. This allows further focus on maternal education, which is crucial for continued effective treatment as well as prevention of additional episodes.

Iron therapy usually is not started until this final phase of treatment so as to prevent binding of iron to already limited stores of transferrin, which, in turn, may interfere with the protein's host defense mechanisms. There also is concern that free iron during the early phase of treatment may exacerbate oxidant damage, precipitating clinical kwashiorkor or marasmic kwashiorkor in a child with clinical marasmus.

Chapter 43 - Obesity

Patricia A. Donohoue

There has been a significant increase in the prevalence of overweight and obesity in the United States, despite nationwide efforts at reducing fat intake to prevent cardiovascular disease. In pediatrics, the consequences of this epidemic are the occurrence of “adult” diseases in youth, such as type 2 diabetes mellitus, hypertension, and hyperlipidemia.

The definition of obesity may vary depending on the source of the information, but most health care providers agree that individuals whose body mass index (BMI) (weight in kilograms divided by the square of the height in meters; kg/m^2) exceeds the age-gender-specific 95th percentile are obese (see Fig. 15–2 *A* and *B*). Those whose BMI is between the 85th and 95th percentiles are overweight and are at increased risk for obesity-related co-morbidities (see also Chapter 41). In adults, it is generally considered that an individual whose BMI is more than 30?kg/m^2 is obese. High BMI correlates with excess body fat in all age groups and in both genders, with the exception of persons with very high muscle mass (e.g., “body builders”). Data for age and gender BMI percentiles are derived from the National Health and Nutrition Examination Survey III (NHANES III) and are available from the Centers for Disease Control and Prevention (www.cdc.gov/nchs/about/major/nhanes).

Etiology.

The regulation of body fat stores and the etiology of human obesity are multifactorial, reflecting complex interactions between genetic background, environmental stimuli, and developmental processes. During the stage of human evolution when food was obtained through strenuous physical activity (e.g., hunting, digging) and periods of prolonged fasting and famine were constant threats, genotypes developed to favor energy storage. In the environment of plentiful and easily accessible high-calorie food, these so-called thrifty genotypes are highly prevalent and, unfortunately, are now detrimental. This gene-environment interaction must be considered in the prevention and treatment of obesity.

An important factor in maintenance of body weight is the relationship between body weight and total energy expenditure. The trend toward returning to a specific set point for body weight is powerful and results not only from a reduction in total energy expenditure in response to weight loss but also from an increase in energy expenditure with weight gain. There are multiple genetic factors controlling this set point. There is ethnic variability in resting energy expenditure; it is higher in white than in black prepubertal girls and higher in white than in black prepubertal children, independent of percent body fat and sex. Genetic factors may also influence the lower physical activity and resting energy expenditure observed in infants who later become obese children. The genetic control of energy expenditure and heat production may be involved in the etiology of obesity. Energy expenditure and heat production are controlled by interactions with sympathetic neurons and mitochondrial uncoupling proteins, among other systems.

The importance of environmental factors on body size is underscored by the marked increase in obesity over the past 20 yr, a time period whose brevity precludes a significant change in the gene pool. The prevalence of obesity is increasing dramatically not only in adults but also in youth, as demonstrated in the Muscatine Study (Table 43–1). The prevalence is significantly higher, and the trend is even more pronounced in minority groups in the United States, particularly in adult females (Table 43–2). The same minority female preponderance occurs in

youth and is particularly apparent at the onset of puberty and at the time of menarche. The pattern of increasing obesity prevalence has been observed throughout the United States and has accelerated over the past 10 yr. The impact of environment on the epidemic of obesity includes unfavorable trends in food intake and physical activity, as well as barriers to reversing these trends. Other examples of the impact of environment on body size are the development of obesity in patients who have survived leukemia or who have suffered hypothalamic damage, especially patients treated for craniopharyngioma.

The importance of heredity on body size has been demonstrated in multiple studies of dizygotic and monozygotic twins and of adopted individuals and their biologic siblings. Studies of twin pairs have consistently demonstrated higher concordance for body size among monozygotic than dizygotic twins. In adult adoptees and their biologic siblings, both full and half siblings, there is a significant correlation of BMI in biologic siblings across the entire distribution of body sizes.

In large unrelated populations from several ethnic groups, there is statistical evidence for recessive gene effects on body size variables, including BMI, abdominal visceral fat, relative fat pattern, and obesity. Longitudinal studies have demonstrated familial aggregation of obesity and cardiovascular risk. Examples of these include the Muscatine Study, the Bogalusa Heart Study, the San Antonio Family Heart Study, the HERITAGE Study, the Québec Family Study, and studies of American Pima Indians.

Epidemiology.

The prediction of risk of adult obesity during childhood is based on several factors. Blood pressure, blood lipid levels, and obesity in childhood track into adulthood. Thus, childhood obesity itself is a predictor of adult obesity and of higher than expected adult morbidity and mortality regardless of the presence of overweight in adulthood. The prevalence of clinically significant obesity-related morbidities in youth is rising and predicts earlier onset of more severe problems in young adults. The increase in type 2 diabetes among children and adolescents is directly related to the obesity epidemic.

Parental obesity, particularly maternal, is predictive of childhood obesity. High birthweight is also a predictor of later obesity, and the most important factor contributing to high birthweight is maternal diabetes and, to a lesser degree, maternal obesity. The relative risk of developing obesity in young adulthood is higher for young children if they have obese parents and higher for older children if they themselves are obese (Table 43–3).

The influence of deficient physical activity on the development of obesity is reflected in the NHANES III data. Lack of physical activity is directly related to television viewing, and hours of television are significantly correlated to weight gain during the growing years. In a study of schoolchildren in California, reduction in television viewing significantly reduced the rate of weight gain in a study of third graders, when compared with third graders with no intervention. Among children 8–16 yr of age, the prevalence of obesity was positively associated with hours of television viewing, even when controlling for age, race, income, caloric intake, and physical activity.

Pathogenesis

ANIMAL MODELS OF SINGLE GENE DEFECTS.

In rodents, multiple examples of naturally occurring single gene mutations producing obesity are known and form the basis for a candidate gene approach to identify the genes responsible for human obesity (Table 43–4). Several human counterparts of these rodent obesity syndromes have been identified. The prototypic obese mice with single gene defects are the obese *(ob/ob,* Lep^{ob} *)* and diabetes (*db/db,* $Lepr^{db}$) autosomal recessive mutations. If present on the same genetic background strain, they cause identical phenotypes of severe hyperphagia, obesity, type 2 diabetes, defective thermogenesis, and infertility due to hypogonadotropic hypogonadism. The mutant gene responsible for the phenotype in Lep^{ob} mice encodes a protein termed *leptin,* which is deficient in these animals. The gene encoding human leptin has been studied extensively, but with the exception of leptin deficiency caused by rare *LEP* gene mutations its importance in altered human satiety and abnormal body size determination has not been clearly demonstrated. Studies of this genetic locus in populations, and in large panels of obese and/or diabetic individuals, have failed to demonstrate linkage or mutations. The cloning of the leptin receptor gene *Lepr* led to characterization of the mutations causing the mouse *db/db* phenotype and its rat homologues, the Zucker fatty (*fa/fa*) and obese Koletsky phenotypes. Thus, mutation of the same gene, *Lepr*, occurred spontaneously in three different strains and produced the same phenotype. Mice that are heterozygous for either the *ob* or the *db* mutation have body composition and leptin homeostasis phenotypes that are intermediate between homozygous wild type and mutant animals. Severe early-onset human obesity caused by a mutant leptin receptor has been identified in three female siblings. These homozygotes had failure of pubertal development and reduced growth hormone and thyroid-stimulating hormone secretion. In

	Corpulent	fa^K	Recessive	5	1p31	Yes	Lepr

ASP = agouti signaling protein; Lepr = leptin receptor; CPE = carboxypeptidase E.

* ASP prevents binding of aMSH to its receptor MC4R. Several MC4R mutations are associated with human obesity.
† *CPE is required for normal prohormone processing by prohormone convertase 1 (PC1). PC1 mutations are associated with human obesity.*

linkage studies of large populations, the leptin receptor locus seems more important than the leptin locus in its contribution to variability in body size.

The tubby *(tub)* mutation in mice is an autosomal recessive trait that is associated with less severe obesity and insulin resistance than *ob* or *db*, is not associated with significant hyperphagia, causes variable degrees of hyperlipidemia depending on background strain, and is more severe in males than females. The phenotype also includes retinal degeneration and sensorineural hearing loss similar to the human Usher, Alström, and Bardet-Biedl syndromes, but human *TUB* mutations have not yet been described.

In the fatty *(fat/fat)* mouse, the recessively inherited mutation causes hyperinsulinemia without hyperglycemia and postpubertal obesity that is less severe than that seen in *ob/ob* or *db/db* mice. The “hyperinsulinemia” is caused by hyperproinsulinemia. The molecular defect is in the gene encoding carboxypeptidase E (CPE), an endoprotease required for normal processing of prohormones to active hormones, including proinsulin to insulin and pro-opiomelanocortin (POMC) to adrenocorticotropic hormone (ACTH), melanocyte-stimulating hormone (MSH), ß-endorphin, and ß-lipoprotein. The role of CPE mutations in human obesity is unknown; however, a possible correlate has been described in which there are mutations of the prohormone convertase 1 (PC1) gene. These patients have obesity along with impaired processing of insulin, leading to diabetes, hyperproinsulinemia, and ACTH deficiency from impaired processing of POMC. Several individuals with mutations of the *POMC* gene have been identified, and they have severe early-onset obesity as well as ACTH deficiency. They also have red hair, whereas their family members do not.

The *yellow* mutation of agouti mice is a dominant trait that causes yellow coat color (rather than the wild-type hairs that are banded black and yellow), obesity, and diabetes. This was the first rodent obesity gene to be cloned, and subsequently dozens of agouti *yellow* alleles have been identified, which vary in their phenotypic expression. The molecular defect in the most dominant form *Ay* is a deletion in the 5' regulatory region. This results in overproduction of agouti signaling protein (ASP) through ectopic expression of normal agouti mRNA in many tissues, rather than its normal site of expression, which is limited to the skin. ASP and another similar peptide, agouti-related peptide (AgRP), act as antagonists of native ligand binding to melanocortin receptors 1–4 (MC1R through MC4R), each of which is expressed differentially in specific tissues. Although ASP mutations have not yet been described in humans, several MC4R mutations are now known to be associated with obesity. Up to 10% of obese subjects (adults and youth) in Germany and France have MC4R mutations. The prevalence rate appears to be lower in the United States. The dominant nature of these mutations is most likely caused by haploinsufficiency and not a dominant negative effect.

CONTROL OF FEEDING.

Energy intake and expenditure is under the control of complex interactions between peripheral signaling and effector systems and neuroendocrine systems. The hormone leptin is an important component of this complex system. Plasma levels of leptin correlate with fat mass and are higher in females than males. As has been demonstrated in animals, human leptin is made almost exclusively in adipose tissue and acts centrally in the hypothalamus by modifying two effector systems. Low

plasma concentrations of leptin and insulin (e.g., during fasting and weight loss) increase food intake and decrease energy expenditure by stimulating neuropeptide Y (NPY) synthesis, and perhaps by inhibiting sympathetic activity and other catabolic pathways. High leptin and insulin concentrations (e.g., during feeding and weight gain) decrease food intake and increase energy expenditure through release of melanocortin and corticotropin-releasing hormone (CRH), among others. The list of neuropeptides that are known to alter energy balance is growing rapidly. Many of these are listed in Table 43–5 . Among the more important peptides that stimulate feeding are orexins A and B, which are secreted by the hypothalamus, and ghrelin, which is secreted by the stomach.

THE HYPOTHALAMIC-PITUITARY-ADRENAL (HPA) AXIS.

It has been demonstrated in multiple animal models that adrenalectomy obliterates or attenuates the obesity syndromes

TABLE 43-5 -- **Central Nervous System Proteins (Neuropeptides) Involved in Energy Homeostasis**

Neuropeptide	Regulation by Adiposity Signal (Leptin or Insulin)
Orexigenic (stimulates feeding)	
Neuropeptide Y[*]	Decreased
Agouti related peptide[*]	Decreased
Melanin-concentrating hormone	Decreased
Orexin A and B (hypocretin 1 and 2)	Decreased
Galanin	Unknown
Norepinephrine	Unknown
Gherlin	Unknown
Anorexigenic (inhibits feeding)	
a-Melanocyte–stimulating hormone[*]	Increased
Corticotropin-releasing hormone[*]	Increased
Thyrotropin-releasing hormone[*]	Increased
Cocaine- and amphetamine-regulated transcript[*]	Increased
Interleukin-1ß[*]	Increased
Urocortin[*]	Unknown

* Exerts effects on both energy intake and expenditure that result in a change in energy stores.

expressed in genetically obese rats and mice, in diet-induced obesity, and in hypothalamic obesity. Treatment with only trace quantities of glucocorticoid causes rapid return of the obesity, indicating heightened sensitivity to the steroid. In humans and animals with hypercortisolemia, obesity is prominent. However, in adrenalectomized animals, the effects seen could result from a combination of glucocorticoid deficiency alone or in combination with the secondary elevation of hypothalamic CRH and pituitary ACTH production. In animal studies, CNS administration of CRH as well as a related hormone, urocortin, mimics the events seen in the “stress response,” including anorexia. These data suggest that therapeutic manipulations of the HPA axis could alter the phenotype of certain genetically obese individuals.

POLYGENIC MODELS.

The polygenic mouse models of obesity have allowed identification of multiple genetic loci within individual strains that modify obesity, plasma cholesterol levels, specific deposition of body fat depots, and propensity toward development of obesity on a high-fat diet. These polygenic models more closely resemble the human obesity phenotypes than single gene models; however, the single gene defects producing recessive traits, dominant traits, promoter alterations, and those subject to parental imprinting must also be considered candidates for genetic effects in human obesity.

GENE-TARGETING AND EFFECTS ON BODY FAT/FEEDING.

Gene targeting of a variety of genes has been used to study obesity. These, along

with other relevant animal models, are summarized in Table 43–6 , and they demonstrate both monogenic and polygenic effects on body size variables.

Clinical Manifestations.

Human obesity in rare instances may be associated with defects at a single genetic locus. These include Prader-Willi, Bardet-Biedl, and Alström syndromes, in which the causes of obesity are unknown. The presence of these syndromes can usually be detected by demonstration of the typical dysmorphic features on physical examination. Certain hormonal aberrations, such as hypothyroidism, Cushing syndrome, and generalized hypothalamic dysfunction, can result in excessive weight gain. However, these conditions are rarely identified among the typical patients who present for evaluation of obesity.

In children, obesity is most often associated with tall stature, slightly advanced bone age, and somewhat early puberty. In most patients with obesity, rapid growth in height precludes the diagnosis of hypothyroidism and hypercortisolism. By contrast, hypothyroidism and cortisol excess cause delayed skeletal development,

TABLE 43-6 -- **Transgenic Models for Altered Body Size or Body Fat**

Increased	Decreased	No Change on Normal Diet
MC4R-KO	Dopamine D_1 receptor KO	CRH KO
5-HT2c receptor KO	UCP-1 overexpression	NPY KO
CRH overexpression	Tyrosine phosphatase 1B KO	TNF-a KO

Nhlh2 gene KO	PPAR ?KO heterozygotes	
11ß-HSD-1 over-expressed in fat		

MC4R = melanocortin receptor 4; KO = knockout; 5-HT2c = 5-hydroxytryptophan 2c; CRH = corticotropin-releasing hormone; BAT = brown adipose tissue; $ß_3$ -AR = $ß_3$ -adrenergic receptor; GLUT4 = glucose transporter 4; NPY = neuropeptide Y; Nhlh2 = one of two helix-loop-helix transcription factors expressed in the developing mouse nervous system; UCP = uncoupling protein; MCH = melanin-concentrating hormone; LPL = lipoprotein lipase; PKA RIIß = protein kinase A regulatory subunit IIß; PPAR = peroxisome proliferator-activated receptor; TNF = tumor necrosis factor; 11ß-HSD-1 = 11-ß-hydroxysteroid dehydrogenase type 1.

short stature, and delayed puberty. Many obese youth also have **acanthosis nigricans,** a hypertrophic hyperpigmentation of the skin most commonly seen on the posterior neck and in skin creases. This condition is associated with insulin resistance and a higher risk of developing type 2 diabetes.

Laboratory Findings, Diagnosis, and Differential Diagnosis.

Obesity can be diagnosed in most cases by simple inspection of the patient. If needed, BMI can be plotted on BMI growth curves (see Fig. 15–2) to identify those who are over the 95th percentile. Early identification of children at risk includes the demonstration of early adiposity rebound. Examination of BMI curves (see Fig. 15–2) shows that BMI reaches a nadir after infancy and then rebounds. If this rebound occurs early, especially if the BMI is already high for age, there is a significantly increased risk of developing obesity.

Hypothyroidism and hypercortisolemia can be ruled out by demonstrating normal free thyroxine and thyroid-stimulating hormone levels and 24?hr urinary free cortisol or diurnal salivary cortisol levels. If patients have severe early-onset obesity, out of proportion to the family history, one of the single gene defects mentioned earlier may need to be considered. Leptin levels can help in the diagnosis of leptin deficiency or resistance, and screening for genetic mutations is possible in several research laboratories.

The most important tests in the evaluation and follow-up of obese patients are those that evaluate cardiovascular disease risk and diabetes risk. These include plasma lipid profiles, fasting glucose and insulin levels, and hemoglobin A1C. It may also be necessary to perform studies to test for sleep apnea.

Complications.

The 2001 Surgeon General's Call to Action

(www.surgeongeneral.gov/topics/obesity/calltoaction) states that there has been a reversal of gains made in cardiovascular health over the recent past, owing to the huge increase in obesity prevalence. Obesity-associated co-morbidities include significantly increased risks for diabetes, cardiovascular disease, cancer, respiratory disease (asthma, sleep apnea), infertility, degenerative joint disease, proteinuria, depression, anxiety, and discrimination both in social life and in the workplace. Obesity shortens life span through its co-morbidities; and the earlier the onset, the shorter the life. It is a chronic disease that requires chronic therapy.

Prevention.

Community-wide efforts need to be directed toward increasing physical activity and changing dietary habits. Increasing the safety of streets and playgrounds may be necessary in some settings, but the resources for this are often absent. Responsibility for promoting and organizing opportunities for nutritional education and for increasing physical activity for all citizens should be shared by schools, community organizations, and places of worship. Enhancement of physical education programs should be a priority of the school systems. School meal programs should provide healthy choices for students; vending machines in schools should not provide high-calorie beverages and snacks. Pediatric health care providers should counsel obese parents about the risk of childhood obesity in their children. Breast-fed infants are less likely to develop adult obesity than bottle-fed infants, and this should be communicated to expectant parents.

Treatment.

Reduction of dietary calories and fat and increasing dietary fiber are recommended. Diets that are lower in carbohydrates may be useful in some individuals, but the basic goal should be reduction in energy intake and increase in energy expenditure. Any increase in physical activity is good, with regular aerobic exercise being the goal. This should be accompanied by a decrease in television viewing and computer games.

MEDICATIONS.

Medical therapeutic options for treatment of obesity are not very promising. Therapy must be long term and ongoing, as is the case with treatment of hypertension and

diabetes. Anti-obesity drugs are not approved for prolonged use or for use in youth. They have not been extensively tested for safety over long periods of time, may only benefit a minority of patients, and may be associated with serious cardiovascular side effects. The major classes of drugs are those that reduce food intake (monoamine oxidase inhibitors, sympathomimetic drugs), those that increase energy expenditure (ephedrine, caffeine), and those that inhibit fat absorption (orlistat). The use of agents to induce dietary fat malabsorption has been only minimally successful and is associated with significant intestinal discomfort if not accompanied by a low-fat diet. Metformin, a glucose-sensitizing agent developed for use in type 2 diabetes, has shown promise in helping obese patients adhere to a diet; the diet itself may be nearly equally effective over the long term. Certain neuropeptide agonists and antagonists are being developed as therapeutic agents. The roles of some of these compounds in energy homeostasis are shown in Table 43–5 .

The use of recombinant leptin in humans resulted in a modest and highly variable loss of weight (loss of fat mass) that was dose related and occurred in both lean and obese subjects. Leptin treatment in the rare leptin-deficient patients produced a rapid reduction in weight and increase in energy expenditure; antibodies to leptin developed after several months of treatment. The impact of these antibodies on efficacy has not yet been demonstrated.

SURGERY.

Surgical therapy to reduce the volume of the stomach may be successful in the long term in some patients. Procedures to bypass the absorptive surfaces of the intestine have been associated with many complications, the most predictable being nutritional deficiencies. Surgery to remove fat (liposuction), if used alone, is not a long-term solution. However, it may be a useful cosmetic adjunct in patients who are successful with diet and exercise, with or without surgical gastroplasty.

GOALS OF TREATMENT.

As with adults, it is rarely possible for obese youth to achieve an “ideal body weight” for height. The initial goal should be a 10% reduction in weight for older children; in adults, this modest degree of loss is associated with a decrease in plasma lipids, blood pressure, fasting insulin, and other co-morbidities such as asthma symptoms. For younger children, severe caloric restriction may result in an unacceptable decrement in height velocity. In many younger children, simply preventing further weight gain for a period of time will achieve the same goals. In all age groups, permanent lifestyle changes are required. This is not unlike the lifestyle changes needed for optimal control of diabetes, hyperlipidemia, and hypertension. The most significant impact on the obesity epidemic will have to be achieved through patient education and prevention. At present, there is limited value for genetic counseling, but there may be an increasing role as more genetic defects are described.

Chapter 44 - Vitamin Deficiencies and Excesses

William C. Heird

Vitamins are essential nutrients that must be supplied exogenously either as part of a well-balanced diet or as supplements. The functions of vitamins are summarized in Table 44–1 , and the daily reference intakes for infants and children are summarized in Table 40–1 . Deficiency states are uncommon in developed countries except, perhaps, among some food-insecure families (see Chapter 42). In contrast, deficiency states (see Table 44–1) are quite common in many developing countries.

Toxicity results from excessive intakes of the fat-soluble vitamins A and D, but toxicity from excessive intakes of the water-soluble vitamins is rare. The vitamin-dependent states are also summarized in Table 44–1 .

VITAMIN A

Vitamin A is a generic term encompassing all ß-ionone derivatives other than provitamin A carotenoids. These include retinol, retinyl ester, retinal and retinoic acid, and the vitamin A alcohol, ester, aldehyde, and acid. *Provitamin A carotenoids* is a generic term for all carotenoids that have the biologic activity of ß-carotene. They or their derivatives with vitamin A activity are required in the diets of adults as well as of infants and children.

ß-Carotene is partially absorbed into the intestinal lymphatics. The remainder is cleaved into two molecules of retinol. Dietary retinyl ester is hydrolyzed to retinol in the intestine, esterified with palmitic acid in the mucosal cells, and stored in the liver as retinyl palmitate, which can be hydrolyzed to free retinol for transport by retinol-binding protein to its site of action. Zinc also is required for this mobilization. Normal plasma values of retinol are 20–50?µg/dL in infants and 30–225?µg/dL in older children and adults.

The liver content of vitamin A is low at birth but is rapidly augmented by the large amounts in colostrum and breast milk as well as infant formulas. Other foods (vegetables, fruits, eggs, butter, liver) or vitamin supplements also provide vitamin A. Cooking, canning, and freezing of foodstuffs results in only small losses of vitamin A, but it is destroyed by oxidizing agents. Thus, risk of vitamin A deficiency is small in healthy children receiving a well-balanced diet. However, vitamin A deficiency can also result from inadequate intestinal absorption secondary to chronic intestinal

disorders or fat malabsorption syndromes. Low dietary intake of fat can also result in low vitamin A absorption, and low dietary protein intake can result in deficient

TABLE 44-1 -- **Physical and Metabolic Properties and Food Sources of the Vitam**

Names and Synonyms	Characteristics	Biochemical Action	Effects of Deficiency	Effects of Excess
Vitamin A: retinol (vitamin A_1) is an alcohol of high molecular weight; 1?µg of retinol = 3.3?IU vitamin A Provitamin A: the plant pigments a-, ß-, and ?-carotenes and cryptoxanthin; ? activity of retinol	Fat soluble; heat stable; destroyed by oxidation, drying; bile necessary for absorption; stored in liver; protected by vitamin E	Component of retinal pigments, rhodopsin and iodopsin, for vision in dim light; bone and tooth development; formation and maturation of epithelia	Nyctalopia, photophobia, xerophthalmia, conjunctivitis, keratomalacia leading to blindness; faulty epiphyseal bone formation; defective tooth enamel; keratinization of mucous membranes and skin; retarded growth; impaired resistance to infection	Anorexia, slow growth, drying and cracking of skin, enlargeme of liver and spleen, swelling and pain of long bones, bone fragility, increas intracranial pressure, alopecia, carotenemia
Vitamin B Complex: thiamine: vitamin B_1 ; antiberiberi vitamin; aneurin	Water and alcohol soluble; fat insoluble; stable in slightly acid solution; labile to heat, alkali, sulfites	Component of thiamine pyrophosphate carboxylases, which act in various oxidative decarboxylations, including that of pyruvic acid	Beriberi, fatigue, irritability, anorexia, constipation, headache, insomnia, tachycardia, polyneuritis, cardiac failure, edema, elevated pyruvic acid in the blood, aphonia	None from oral intake
Riboflavin: vitamin B_2	Sparingly soluble in water; sensitive to light and alkali; stable to heat, oxidation, acid	Constituent of flavoprotein enzymes important in hydrogen transfer reactions; amino acid, fatty acid, and carbohydrate metabolism and cellular respiration. Retinal pigment for light adaptation	Ariboflavinosis; photophobia, blurred vision, burning and itching of eyes, corneal vascularization, poor growth, cheilosis	Not harmful
Niacin: nicotinamide; nicotinic acid; antipellagra vitamin	Water and alcohol soluble; stable to acid, alkali, light, heat, oxidation	Constituent of coenzymes I and II. NAD, NADP cofactors in a number of dehydrogenase systems	Pellagra, multiple B-vitamin deficiency syndrome, diarrhea, dementia, dermatitis	Nicotinic acid (r the amide) is vasodilator; skin flushing and itching; hepatopathy
Folacin: group of related compounds containing pteridine ring, para-amino benzoic acid, and glutamic acid. Pteroylglutamic acid (PGA)	Slightly soluble in water: labile to heat, light, acid	Concerned with formation and metabolism of one-carbon units; participates in synthesis of purines, pyrimidines, nucleoproteins, and methyl groups	Megaloblastic anemia (infancy, pregnancy) usually is secondary to malabsorption disease, glossitis, pharyngeal ulcers, impaired immunity	Unknown

Cyanocobalamin: vitamin B_{12}	Slightly soluble in water; stable to heat in neutral solution; labile in acid or alkaline ones; destroyed by light. Castle intrinsic factor of the stomach required for absorption	Transfer of one-carbon units in purine and labile methyl group metabolism; essential for maturation of red blood cells in bone marrow; metabolism of nervous tissue; adenosylcobalamin is the coenzyme for methylmalonyl CoA mutase	Juvenile pernicious anemia, due to defect in absorption rather than to dietary lack; also secondary to gastrectomy, celiac disease, inflammatory lesions of small bowel, long-term drug therapy (PAS, neomycin); methylmalonic aciduria; homocystinuria	Unknown
Biotin	Crystallized from yeast; soluble in water	Coenzyme carboxylases; involved in CO_2 transfer	Dermatitis, seborrhea; inactivated by avidin in raw egg white	None known
Vitamin B_6 active forms: pyridoxine, pyridoxal, pyridoxamine	Water soluble; destroyed by ultraviolet light and by heat	Constituent of coenzymes for decarboxylation, ransamination, transsulfuration; fatty acid metabolism	Irritability, convulsions, hypochromic anemia; peripheral neuritis in patients receiving isoniazid; oxaluria	Sensory neuropathy
Vitamin C: ascorbic acid; vitamin C; antiscorbutic vitamin	Water soluble; easily oxidized, ccelerated by heat, light, alkali xidative enzymes, traces of opper or iron	Integrity and maintenance of ntercellular material; facilitates bsorption of iron and conversion f folic acid to folinic acid; etabolism of tyrosine and henylalanine; activity of succinic ehydrogenase and serum hosphatase in infants, not in dults	Scurvy and poor wound healing	Oxaluria

Vitamin D: group of sterols aving similar physiologic ctivity, D_2 -calciferol is ctivated ergosterol. D_3 is ctivated 7-dehydrocholesterol in skin.1thinsp;µg = 40?IU vitamin D	Fat soluble, stable to heat, acid alkali, and oxidation; bile ecessary for absorption. Prohormone for 25-OH cholecalciferol	Regulates absorption and deposition of calcium and phosphorus by affecting permeability of intestinal membrane; regulates level of erum alkaline phosphatase, hich is believed to be concerned with calcium phosphate deposition in bones and teeth	Rickets (high serum phosphatase level appears before bone deformities); nfantile tetany; poor growth; steomalacia	Wide variation i tolerance; over 500?µg/24?hr toxic when continued for weeks; prolong administration c 45?µg/24?hr m be toxic; nause diarrhea, weigh loss, polyuria, nocturia, calcification of soft tissues, including heart, renal tubules, blood vessels, bronchi, stomac
Vitamin E: group of related hemical compounds—tocopherols with similar biologic activities	Fat soluble; unstable to ultraviolet light, alkali; readily oxidized by oxygen, iron, rancid fats Antioxidant; bile necessary for absorption	Minimizes oxidation of carotene, vitamin A, and linoleic acid; stabilizes membranes	Requirements related to polyunsaturated fat intake; red blood cell hemolysis in premature infants; loss of neural integrity	Unknown
Vitamin K: group of aphthoquinones with similar biologic activities; K_1 is phytoquinone	Natural compounds are fat soluble; stable to heat and reducing agents; labile to oxidizing agent, strong acids, alkali, light; bile salts necessary for intestinal absorption	Prothrombin formation; coagulation factors II, VII, IX, and X and osteocalcin are vitamin K–dependent; proteins C, S, Z	Hemorrhagic manifestations; bone etabolism	Not established analogues may roduce hyperbilirubiner in remature infants

NAD(P) = nicotinamide adenine dinucleotide (phosphate); CoA = coenzyme A; PAS = para-aminos

retinol-binding protein and, hence, a low plasma concentration of vitamin A.

The major role of vitamin A is in vision. The human retina contains two distinct photoreceptor systems—the rods, which are sensitive to light of low intensity, and the cones, which are sensitive to colors and to light of high intensity. Retinal is the

prosthetic group of the photosensitive pigment in both. The major difference between the visual pigments in rods (rhodopsin) and in cones (iodopsin) is the nature of the protein bound to retinal. All-*trans*-retinal isomerizes in the dark to 11 *cis*-retinal, which combines with opsin to form rhodopsin. Energy from light quanta reconverts 11-*cis*-retinal to the all-*trans* form, and this energy exchange is transmitted via the optic nerve to the brain, resulting in visual sensation.

Retinoids, in addition to involvement in vision, are essential for cell differentiation, activation of retinoic acid–responsive genes, and membrane stability. Vitamin A also plays a role in keratinization, cornification, bone metabolism, placental development, growth, spermatogenesis, and mucus formation. Characteristic changes of deficiency in epithelium include proliferation of basal cells, hyperkeratosis, and the formation of stratified, cornified squamous epithelium. Epithelial changes in the respiratory system may result in bronchiolar obstruction. Squamous metaplasia of the renal pelves, ureters, urinary bladder, enamel organs, and pancreatic and salivary ducts may lead to an increase in infections in these areas.

Vitamin A Deficiency

Clinical Manifestations.

Ocular lesions of vitamin A deficiency develop insidiously and rarely occur before 2–3 yr of age. The posterior segment of the eye is affected initially with impairment of dark adaptation, resulting in night blindness. Later, drying of the conjunctiva (xerosis conjunctivae) and cornea (xerosis corneae) occur, followed by wrinkling and cloudiness of the cornea or keratomalacia (Fig. 44–1). Dry, silver-gray plaques may appear on the bulbar conjunctiva (Bitot spots), with follicular hyperkeratosis and photophobia.

Vitamin A deficiency also may result in retardation of mental and physical growth and in apathy. Anemia with or without hepatosplenomegaly is usually present. The skin is dry and scaly, and follicular hyperkeratosis may be found on the shoulders, buttocks, and extensor surfaces of the extremities. The vaginal epithelium may become cornified, and epithelial metaplasia of the urinary tract may result in pyuria and hematuria. Increased intracranial pressure with wide separation of cranial bones at the sutures may occur, but hydrocephalus, with or without paralyses of the cranial nerves, is an infrequent manifestation of vitamin A deficiency.

Figure 44-1 Recovery from xerophthalmia, showing permanent eye lesion. (From Bloch CE: Blindness and other diseases arising from deficient nutrition [lack of fat-soluble A factor]. *Am J Dis Child* 1924;27:139.)

Diagnosis.

Dark adaptation tests may be helpful in diagnosing vitamin A deficiency. Xerosis conjunctivae can be detected by biomicroscopic examination of the conjunctiva. Examination of the scrapings from the eye and vagina is recommended as a diagnostic aid. The plasma carotene concentration falls quickly, but that of vitamin A decreases more slowly.

Prevention.

Infants should receive at least 500?µg of vitamin A daily, and older children, like adults, should receive 600–1500?µg of vitamin A or carotene. Because maternal vitamin A status is reflected in breast milk vitamin A content, mothers of breast-fed infants living in regions where vitamin A deficiency is common should be given 30,000?µg [100,000?IU]) of vitamin A postpartum.

Low-fat diets should be supplemented with vitamin A. In disorders with poor absorption of fat or increased excretion of vitamin A, water-miscible preparations should be administered in amounts several times the usual reference daily intake. Premature infants, who absorb fats and vitamin A less efficiently than do term infants, should also receive water-miscible preparations.

Epidemiologic public health studies in areas of the world where overt or subclinical vitamin A deficiency is prevalent because of insufficient dietary intake, seasonal variance, or intercurrent illness have shown that restoration of vitamin A sufficiency is associated with a 20% increase in survival of deficient children. Effects are not apparent in infants less than 6 mo of age, but older infants supplemented every 4 mo with water-miscible vitamin A, 30,000?µg (100,000?IU), in those between 6 and 11 mo of age and 60,000?µg (200,000?IU) in those older than 12 mo of age, have a lower mortality associated with severe diarrhea and measles. No consistent effect of vitamin A supplementation on the severity or mortality of respiratory disease has been reported. The effect of vitamin A on mortality from infectious diseases may be related to restoration of epithelial integrity and/or upregulation of immunocompetence.

Treatment.

A daily supplement of 1,500?µg of vitamin A is sufficient for treating latent vitamin A deficiency. Xerophthalmia is treated by giving 1,500?µg/kg orally for 5 days followed by daily intramuscular injection of 7,500?µg of vitamin A in oil until recovery occurs. Morbidity and mortality rates from viral infections such as measles may be lower in nondeficient children who are given daily doses of 1,500–3,000?µg of vitamin A.

Hypervitaminosis A

Clinical Manifestations.

Acute hypervitaminosis A may occur in infants after ingesting 100,000?µg or more. The symptoms are nausea, vomiting, drowsiness, and, in young infants, bulging of

the fontanel. Diplopia, papilledema, cranial nerve palsies, and other symptoms suggestive of brain tumor (pseudotumor cerebri) may also be present. Toxicity has occurred with supplementation during vaccine administration in developing countries.

Chronic hypervitaminosis A results from ingestion of excessive doses for several weeks or months. An affected child has anorexia, pruritus, and a lack of weight gain. Irritability, limitation of motion, with tender swelling of the bones, alopecia, seborrheic cutaneous lesions, fissuring of the corners of the mouth, increased intracranial pressure, and hepatomegaly also may develop. Craniotabes and desquamation of the palms and soles are common. Radiographs show hyperostosis affecting several long bones; it is most notable at the middle of the shafts (Fig. 44–2). A history of excessive ingestion of vitamin A helps to differentiate vitamin A toxicity from cortical hyperostosis (see Chapter 688). In addition, the serum vitamin A level is elevated. Hypercalcemia and/or liver cirrhosis may occasionally be seen.

Severe congenital malformations may occur in infants of mothers who consume large amounts of oral retinoids for treatment of acne.

Ingested carotenoids, although nontoxic, may result in yellow discoloration of the skin but not of the sclera. This disorder, *carotenemia,* is especially likely to occur in children with liver disease, diabetes mellitus, or hypothyroidism and in those who have congenital absence of enzymes that convert provitamin A carotenoids.

VITAMIN B COMPLEX

Vitamin B complex includes several factors of differing chemical composition and function: thiamine (vitamin B_1), riboflavin, niacin, pyridoxine (vitamin B_6), biotin, folate, and vitamin B_{12} . All are important constituents of enzyme systems that are closely related functionally. Hence, lack of a single factor can interrupt

Figure 44-2 Hyperostosis of the ulna and the tibia in an infant 21 mo of age, resulting from vitamin A poisoning. *A,* Long, wavy cortical hyperostosis of the ulna. *B,* Long, wavy cortical hyperostosis of the right tibia; striking absence of metaphyseal changes. (From Caffey J: *Pediatric X-ray Diagnosis,* 5th ed. Chicago, Year Book, 1967, p 994.)

an entire chain of chemical processes, producing diverse clinical manifestations.

Diets deficient in any one of the B complex vitamins are frequently poor sources of other B vitamins, and manifestations of several vitamin B deficiencies can usually be found in the same person. Because of this, it is generally practical to treat a patient with evidence of deficiency of a specific B vitamin with the entire complex of B vitamins.

Factors such as pantothenic acid, choline, and inositol are important for normal functioning of the human organism, but at present no specific deficiency syndromes can be ascribed to their lack in the diets of children.

Thiamine

Thiamine (vitamin B_1) is water soluble and, as thiamine pyrophosphate or cocarboxylase, functions as a coenzyme in carbohydrate metabolism. It also is required for the synthesis of acetylcholine, and deficiency results in impaired nerve conduction. It is the coenzyme in transketolation and in decarboxylation of a-keto acids and, hence, participates in the hexose monophosphate shunt that generates nicotinamide adenine dinucleotide phosphate and pentose.

Breast milk and bovine milk as well as vegetables, cereals, fruits, and eggs are good sources of thiamine. Thus, most infants and older children whose diets contain these foods do not require thiamine supplements. On the other hand, breast-fed infants of thiamine-deficient mothers are at risk for deficiency. In addition, thiamine is easily destroyed by heat, particularly in neutral or alkaline media; therefore, it is readily extracted from food by cooking water. Furthermore, because the covering of cereal contains most of the vitamin, polishing reduces its availability.

Thiamine absorption from the gastrointestinal tract usually is excellent but may be low in those with gastrointestinal or liver disease. Fever, surgery, and/or stress increase the requirement for thiamine but, because these events are rarely present for very long, they are not likely to result in deficiency.

Thiamine dependence has been described in a child with megaloblastic anemia and in an infant with otherwise typical maple syrup urine disease. In addition, the urine of children with Leigh encephalomyelopathy as well as that of their parents inhibits the formation of thiamine pyrophosphate and large doses of thiamine improve some of the physical abnormalities associated with the disease.

Thiamine Deficiency

Clinical Manifestations.

Early manifestations of thiamine deficiency include fatigue, apathy, irritability, depression, drowsiness, poor mental concentration, anorexia, nausea, and abdominal discomfort. Signs of progression include peripheral neuritis with tingling, burning, and paresthesias of the toes and feet, decreased deep tendon reflexes, loss of vibration sense, tenderness and cramping of leg muscles, congestive heart failure, and psychic disturbances. Patients may have ptosis of the eyelids and atrophy of the optic nerve. Hoarseness or aphonia caused by paralysis of the laryngeal nerve is a characteristic sign. Muscle atrophy and tenderness of nerve trunks are followed by ataxia, loss of coordination, and loss of deep sensation. Paralysis occurs in adults but is uncommon in children. Later signs include increased intracranial pressure, meningismus, and coma.

The full-blown deficiency state is called **beriberi**. Two forms of the condition, based primarily on appearance of the patient, are often discussed: wet beriberi and dry beriberi. The child with wet beriberi is undernourished, pale, edematous with dyspnea, vomiting, and tachycardia, and has a waxy skin; the urine often contains albumin and casts. The child with dry beriberi appears plump but is pale, flabby, and listless with dyspnea, tachycardia, and hepatomegaly.

Death from thiamine deficiency usually is secondary to cardiac involvement. The

initial signs are slight cyanosis and dyspnea, but tachycardia, enlargement of the liver, loss of consciousness, and convulsions may develop rapidly. The heart, especially the right side, is enlarged. The electrocardiogram shows an increased QT interval, inverted T waves, and low voltage. These changes as well as the cardiomegaly rapidly revert to normal with treatment, but, without prompt treatment, cardiac failure can develop rapidly and result in death.

In fatal cases of beriberi, lesions are located principally in the heart, peripheral nerves, subcutaneous tissue, and serous cavities. The heart is dilated, and fatty degeneration of the myocardium is common. Generalized edema or edema of the legs, serous effusions, and venous engorgement are often present. Degeneration of myelin and axon cylinders of peripheral nerves with wallerian degeneration beginning in the distal locations also is common, particularly in the lower extremities. Lesions in the brain include vascular dilatation and hemorrhage.

Diagnosis.

The early symptoms of thiamine deficiency are common in many types of nutritional disturbances and, therefore, are not helpful in diagnosing thiamine deficiency. Low red blood cell transketolase and high blood or urinary glyoxylate levels are useful diagnostic indicators. Measurement of urinary thiamine excretion or urinary excretion of its metabolites, thiazole or pyrimidine, after an oral loading dose of thiamine may help to identify the deficiency state. Clinical response to administration of thiamine is the best test for thiamine deficiency.

Prevention.

A maternal diet containing sufficient amounts of thiamine prevents thiamine deficiency in breast-fed infants, and infant formulas marketed in all developed countries contain adequate thiamine. A varied diet containing fresh fruits and vegetables as well as whole grain cereals after the period of exclusive breast-feeding or formula feeding will help assure adequate thiamine intake without supplementation. Thiamine requirements are higher if the carbohydrate content of the diet is high, but this is rarely a problem.

Treatment.

If a breast-fed infant develops beriberi, both the mother and child should be treated with thiamine. The daily dose for children and adults, respectively, is 10?mg and 50?mg. In the absence of gastrointestinal disturbances, oral administration is effective. However, thiamine should be given intramuscularly or intravenously to children with cardiac failure. Such treatment is usually followed by dramatic improvement, although complete cure requires several weeks of treatment. The heart is not permanently damaged.

Patients with beriberi often have other B complex vitamin deficiencies; therefore, all other vitamins of the B complex also should be administered.

Riboflavin

Riboflavin is a yellow, fluorescent, water-soluble substance that is stable to heat and acid but is destroyed by light and alkali. The coenzymes flavin mononucleotide and flavin adenine dinucleotide (FAD), which form the prosthetic groups of several enzymes important in electron transport, are synthesized from riboflavin. Thus, riboflavin is essential for growth and tissue respiration. It also may play a role in light adaptation, and it is required for conversion of pyridoxine to pyridoxal phosphate. Large amounts are found in liver, kidney, brewer's yeast, milk, cheese, eggs, and leafy vegetables. Cow's milk contains about five times as much riboflavin as human milk.

Riboflavin Deficiency

Riboflavin deficiency, without deficiencies of other members of the vitamin B complex, is rare. It is usually caused by inadequate riboflavin intake, but faulty absorption may contribute in patients with biliary atresia or hepatitis as well as in those receiving probenecid, phenothiazines, or oral contraceptives. Phototherapy destroys riboflavin.

Clinical Manifestations.

Signs and/or symptoms of riboflavin deficiency include cheilosis (perlèche), glossitis, keratitis, conjunctivitis, photophobia, lacrimation, marked corneal vascularization, and seborrheic dermatitis. Cheilosis begins with pallor at the angles of the mouth and progresses to thinning and maceration of the epithelium. Superficial fissures, often covered by yellow crusts, develop in the angles of the mouth, and extend radially into the skin for distances of 1–2?cm. With glossitis, the tongue is smooth with loss of papillary structure. A normocytic, normochromic anemia with bone marrow hypoplasia is common.

Diagnosis.

The signs and symptoms of riboflavin deficiency are too nonspecific to make a definitive diagnosis. Useful diagnostic tests include urinary excretion of riboflavin below 30?µg/24?hr and low levels of erythrocyte glutathionine reductase, a flavoprotein requiring FAD.

Prevention.

Reference daily intakes of riboflavin are presented in Table 40–1 . Deficiency is usually prevented by a diet that contains adequate amounts of milk, eggs, leafy vegetables, and lean meats.

Treatment.

Treatment includes oral administration of 3–10?mg of riboflavin daily. If no response occurs within a few days, intramuscular injections of 2?mg of riboflavin in saline may be given as often as three times daily. The child should also be given a well-balanced diet, including, at least temporarily, generous supplements of other B

complex vitamins.

Niacin

Niacin forms part of two cofactors, nicotinamide adenine dinucleotide and nicotinamide adenine dinucleotide phosphate, that are important in electron transfer and glycolysis. Although dietary tryptophan can partially substitute for niacin, other sources of niacin are necessary. Good sources include liver, lean pork, salmon, poultry, and red meat. Most cereals contain only small amounts. Milk and eggs contain little niacin but are good sources of tryptophan from which the active cofactors can be synthesized. Only small losses of niacin occur in cooking.

Niacin Deficiency

Pellagra (*pellis,* "skin"; *agra,* "rough"), a deficiency disease caused by a lack of niacin (nicotinic acid), affects all tissues of the body. It occurs chiefly in countries where corn (maize), a poor source of tryptophan, is a basic foodstuff.

Clinical Manifestations.

The early symptoms of pellagra are vague. Anorexia, lassitude, weakness, burning sensations, numbness, and dizziness may be prodromal symptoms. After a long period of deficiency, the classic triad of dermatitis, diarrhea, and dementia appears. Manifestations in children with parasites or chronic disorders may be especially severe.

The dermatitis is the most characteristic manifestation of pellagra. This may develop suddenly or insidiously and may be elicited by irritants, including intense sunlight. The lesions first appear as symmetric areas of erythema on exposed surfaces resembling sunburn. Thus, in mild cases, the dermatitis may not be recognized. The lesions are usually sharply demarcated from the healthy skin around them, and the distribution of the lesions may change frequently. The lesions on the hands often have the appearance of a glove (pellagrous glove). Similar demarcations may also occur on the foot and leg (pellagrous boot) or around the neck (Casal necklace; Fig. 44–3). In some cases, vesicles and bullae develop (wet type); in others, there may be suppuration beneath the scaly, crusted epidermis and, in still others, the

Figure 44-3 Pellagra showing an early lesion on the neck (Casal necklace).

swelling may disappear after a short time followed by desquamation. The healed parts of the skin may remain pigmented.

The cutaneous lesions may be preceded by or accompanied by stomatitis, glossitis, vomiting, and/or diarrhea. Swelling and redness of the tip of the tongue and its lateral margins is often followed by intense redness, even ulceration, of the entire tongue and papillae.

Nervous symptoms include depression, disorientation, insomnia, and delirium.

The classic symptoms of pellagra are usually not well developed in infants and young children, but anorexia, irritability, anxiety, and apathy are common. They may also have sore tongues and lips, and their skin is usually dry and scaly. Diarrhea and constipation may alternate, and a moderate secondary anemia may occur. Children who have pellagra often have evidence of other nutritional deficiency diseases.

Pathology.

Histologically, there is edema and degeneration of the superficial collagen of the dermis. The papillary vessels are engorged, and there is perivascular lymphocytic infiltration. The epidermis is hyperkeratotic and later becomes atrophic. Changes similar to those in the skin also are present in the tongue, buccal mucous membranes, and vagina. These may be associated with secondary infection and ulceration.

The walls of the colon are thickened and inflamed with patches of pseudomembrane and, usually, mucosal atrophy. Changes in the nervous system occur relatively late in the disease. These include patchy areas of demyelination and degeneration of ganglion cells; demyelination of both the posterior and lateral columns may be seen in the spinal cord.

Diagnosis.

Diagnosis is usually made from the physical signs of glossitis, gastrointestinal symptoms, and a symmetric dermatitis. Rapid clinical response to niacin is an important confirming test. *N*-methylnicotinamide, a normal metabolite of niacin, is almost undetectable in the urine of niacin-deficient individuals.

Prevention.

A well-balanced diet containing meat, vegetables, eggs, and milk easily provides adequate intakes of niacin (see Table 40–1). Thus, supplements of niacin are necessary only in breast-fed infants whose mothers have pellagra or in children on very restricted diets.

Treatment.

Children usually respond rapidly to antipellagral therapy. A liberal and well-balanced diet should be supplemented with 50–300?mg of niacin daily; in severe cases or in cases of poor intestinal absorption, 100?mg may be given intravenously. Large doses of niacin are often followed by a sensation of heat as well as flushing and burning of the skin. These unpleasant effects, which occur within a half hour of niacin ingestion, are not produced by niacinamide. Large doses of niacin also may cause cholestatic jaundice or hepatotoxicity.

The diet also should be supplemented with other vitamins, especially other B

complex vitamins. Sun exposure should be avoided during the active phase of pellagra, and the skin lesions may be covered with soothing applications. Hypochromic anemia, if present, should be treated with iron. Even after successful treatment, the diet should be supervised continuously to prevent recurrence.

Pyridoxine (Vitamin B_6)

Vitamin B_6 includes pyridoxal, pyridoxine, and pyridoxamine. These are converted to pyridoxal-5-phosphate (or pyridoxamine-5-phosphate), which acts as a coenzyme in decarboxylation and transamination of amino acids (e.g., in the decarboxylation of 5-hydroxytryptophan in the formation of serotonin) and in the metabolism of glycogen and fatty acids. Vitamin B_6 also is essential for the breakdown of kynurenine. When this does not occur, xanthurenic acid appears in the urine. In addition, pyridoxine is necessary for adequate functioning of the nervous system. Pyridoxal phosphate is the coenzyme for both glutamic decarboxylase and ?-aminobutyric acid transaminase, each of which is necessary for normal brain metabolism. Other roles of pyridoxine include participation in active transport of amino acids across cell membranes, chelation of metals, and synthesis of arachidonic and docosahexaenoic acids from linoleic and linolenic acids, respectively. If it is lacking, glycine metabolism may lead to oxaluria. Pyridoxine is excreted largely as 4-pyridoxic acid. The pyridoxine content of human milk and infant formulas is adequate. Bovine milk and cereals also are good sources of pyridoxine, but prolonged heat processing of this milk and cereal destroys it. Diseases with fat malabsorption may contribute to vitamin B_6 deficiency.

Pyridoxine antagonists (e.g., isoniazid used in the treatment of tuberculosis), pregnancy, and drugs such as penicillamine, hydralazine, and the oral progesterone-estrogen contraceptives increase the requirements for pyridoxine.

Pyridoxine Deficiency

Clinical Manifestations.

There are several types of *vitamin B_6 dependence syndromes.* These include vitamin B_6 –dependent convulsions, a vitamin B_6 –responsive anemia, xanthurenic aciduria, cystathioninuria, and homocystinuria. They result, presumably, from errors in enzyme structure or function, and patients with these syndromes respond to very large amounts of pyridoxine. *Deficiency symptoms* secondary to one of the vitamin B_6 dependence syndromes or inadequate intake are not as common in children as in adults. Four clinical disturbances caused by vitamin B_6 deficiency have been described in humans: convulsions in infants, peripheral neuritis, dermatitis, and anemia. Pyridoxine and folic acid decrease the frequency of thrombotic events in adults with elevated serum homocysteine levels.

Infants fed a formula deficient in vitamin B_6 for 1 to 6 mo exhibit irritability and generalized seizures. Gastrointestinal distress and an aggravated startle response also are common. Peripheral neuropathy may occur during treatment of tuberculosis with isonicotinic acid hydrazide (INH). The neuropathy responds to administration of pyridoxine or to a decrease in the dose of the drug. Skin lesions include cheilosis, glossitis, and seborrhea around the eyes, nose, and mouth. Microcytic anemia, oxaluria, oxalic acid bladder stones, hyperglycinemia, lymphopenia, decreased antibody formation, and infections also occur.

Convulsions due to vitamin B_6 dependence may occur within several hours to as long as 6 mo after birth. The seizures, typically, are myoclonic with a hypsarrhythmic electroencephalographic (EEG) pattern. In many cases, the mother received large doses of pyridoxine during pregnancy for control of emesis.

In vitamin B_6 –dependent anemia, the red blood cells are microcytic and hypochromic. Patients have elevated serum iron concentrations, saturation of iron-binding protein, hemosiderin

deposits in bone marrow and liver, and failure of iron utilization for hemoglobin synthesis.

Xanthurenic aciduria after a tryptophan load occurs normally in some families and is apparently benign. Xanthurenic acid excretion decreases after large doses of vitamin B_6 . *Cystathioninuria* also is not accompanied by any clear clinical disturbance, although cystathionase is a vitamin B_6 –dependent enzyme (see Chapter 73.3).

Cystathionine ß-synthase also is a vitamin B_6 –dependent enzyme (see Chapter 73.3). In some patients with homocystinuria, serum levels of homocysteine decline after vitamin B_6 administration.

Anemia is not common in infants with pyridoxine deficiency. After administration of 100?mg/kg of tryptophan, large amounts of xanthurenic acid appear in the urine of patients with pyridoxine deficiency; none appears in the urine of normal individuals. Xanthurenic acid excretion also may not increase after a tryptophan load in patients with pyridoxine dependence.

Diagnosis.

All infants with seizures should be suspected of having vitamin B_6 deficiency or dependence. If more common causes of infantile seizures (e.g., hypocalcemia, hypoglycemia, infection) are eliminated, 100?mg of pyridoxine should be injected. If the seizure stops, vitamin B_6 deficiency should be suspected and a tryptophan loading test should be performed. In older children, 100?mg of pyridoxine may be injected intramuscularly while the EEG is being recorded; a favorable response of the EEG suggests pyridoxine deficiency.

Erythrocyte glutamic pyruvic transaminase is low in pyridoxine deficiency. Hence, its concentration may be a useful indicator of vitamin B_6 status.

Prevention.

Balanced diets usually contain sufficient pyridoxine to prevent deficiency, but children receiving a high-protein diet may require supplemental vitamin B_6 . Infants whose mothers have received large doses of pyridoxine during pregnancy are at increased risk of seizures from pyridoxine dependence, and supplements during the first few weeks of life should be considered. Any child receiving a pyridoxine antagonist such as isoniazid should be carefully observed for neurologic manifestations; if these develop, pyridoxine should be administered or the dose of the antagonist should be decreased. A daily intake of 0.3–0.5?mg of pyridoxine in an infant, 0.5–1.5?mg in a child, and 1.5–2.0?mg in an adult prevents deficiency states. However, larger amounts may be necessary in pyridoxine dependency.

Treatment.

Convulsions due to pyridoxine deficiency should be treated with 100?mg of the vitamin given intramuscularly. One dose should suffice if the diet is adequate. For pyridoxine-dependent children, daily doses of 2–10?mg intramuscularly or 10–100?mg orally may be necessary.

Pyridoxine Toxicity

Megadoses of pyridoxine have caused neuropathy in adults.

Biotin

Biotin is discussed in Chapter 74.6 . Many microorganisms produce biotin. Therefore, biotin deficiency is rare. Deficiency may occur in those consuming the biotin antagonist avidin, found in raw egg white. Deficiency also has been described in infants and children receiving parenteral nutrition exclusively and in infants whose mothers are biotin deficient.

Brawny dermatitis, orofacial lesions, alopecia, somnolence, hallucinations, hypotonia, and hyperesthesia with accumulation of organic acids are common manifestations of deficiency. Other neurologic signs may occur.

Biotin deficiency is suggested by organic aciduria, particularly propionic and dicarboxylic acids. Response of clinical and biochemical abnormalities to biotin administration is confirmatory.

Inclusion of biotin in parenteral nutrition infusates will prevent the most common cause of biotin deficiency in infants. Oral administration of 10?mg is sufficient for treatment of deficiency as well as to confirm the diagnosis of deficiency.

Folic Acid

Folic acid is required primarily for its hematologic effects, which are discussed in Chapter 446 .

Folate deficiency before becoming pregnant or during pregnancy results in serious dysmorphologic effects in the fetus. Neurotube defects are among the most common such effects. Consumption of 400?µg of folic acid daily during the periconceptional period markedly decreases the incidence of neurotube and other anatomic defects and may lower the incidence of premature labor. Food may be fortified with folate as a preventive measure to decrease the incidence of neurotube defects. Sufficient fortification to achieve an intake of 100–200?µg/24?hr has been suggested. Cereals and grains are the most commonly fortified food products. It also has been suggested that all women of childbearing age receive a daily folate supplement of 400?µg.

Thrombotic events related to slightly elevated levels of homocystine in adults may be decreased by daily consumption of 1?mg of folic acid together with 5–100?mg of pyridoxine. However, supplements with betaine and vitamin B_{12} may be required to normalize homocystine levels. These doses are considerably less than those given for the inborn error of metabolism homocystinuria (see Chapter 73.3).

Vitamin B_{12}

See Chapters 320 and 446 .

VITAMIN C (ASCORBIC ACID)

Ascorbic acid, a potent reducing agent, functions in a number of enzyme systems (see Table 44–1 and Chapter 73.2). For example, transient hypertyrosinemia of the newborn, which is relatively common among low-birthweight infants and to a lesser extent in term infants fed high-protein diets, can be corrected by administering ascorbic acid (see Chapter 73.2). Ascorbic acid also is necessary for conversion of folic acid or other conjugates (see Table 44–1 and Chapters 446 and 320); thus, deficiency may be a factor in some cases of megaloblastic anemia. The major role of ascorbic acid, however, is in the formation of normal collagen. The defects in collagen structure arising from deficiency of the vitamin are due, in part, to failure to incorporate hydroxyproline and proline into collagen, and the resulting alterations in collagen account for the major metabolic and clinical manifestations of vitamin deficiency.

If the mother's intake of vitamin C during pregnancy is adequate, her infant will have adequate stores of vitamin C at birth. The vitamin C content of cord blood plasma is usually two to four times that of maternal plasma. Breast milk produced by a vitamin C–sufficient mother contains adequate vitamin C, as do all infant formulas. However, low maternal vitamin C intake may result in a low breast milk content of the vitamin. Bovine milk contains very little vitamin C; thus, infants fed bovine milk and evaporated milk formulas must receive vitamin C supplements. Fresh fruits, especially citrus fruit, and vegetables are good sources of vitamin C.

The need for vitamin C is increased by febrile illnesses, particularly infectious and diarrheal diseases. Iron deficiency, cold exposure, and protein depletion also increase the need for vitamin C.

Vitamin C Deficiency

Pathophysiology.

Vitamin C deficiency results in scurvy, a condition in which formation of collagen and chondroitin sulfate is

impaired. This results in a tendency to hemorrhage, defective tooth dentin, and loosening of the teeth. Also, because osteoblasts cannot form osteoid, endochondral bone formation cannot proceed. In addition, the bony trabeculae that have been formed become brittle and fracture easily. The periosteum becomes loosened and subperiosteal hemorrhage occurs, especially at the ends of the femur and tibia. Severe deficiency may result in degeneration of skeletal muscles, cardiac hypertrophy, bone marrow depression, and adrenal atrophy.

Clinical Manifestations.

Scurvy can occur at any age but, because clinical manifestations require time to develop, it is unusual in newborn infants. The usual age at onset is between 6 and 24 mo. After variable periods of vitamin C inadequacy, vague symptoms such as irritability, tachypnea, digestive disturbances, and loss of appetite appear. Usually, there is evidence of generalized tenderness. This is particularly noticeable in the legs when the infant is picked up or when the diaper is changed. The pain results in pseudoparalysis; the legs are usually held in a froglike position with the hips and knees semiflexed with the feet rotated outward. Edematous swelling along the shafts of the legs may be present and, in some cases, a subperiosteal hemorrhage can be felt at the end of the femur. The affected child's facial expression is apprehensive. Changes in the gums are most noticeable after teeth have erupted. These include bluish purple, spongy swellings of the mucous membrane, especially over the upper incisors. A "rosary" at the costochondral junctions and depression of the sternum are other typical features (Fig. 44–4). The angulation of scorbutic beads is usually sharper than that of a rachitic rosary.

Figure 44-4 Scorbutic rosary and depression of sternum.

Petechial hemorrhages are often present in the skin and mucous membranes. Hematuria, melena, and orbital or subdural hemorrhages also may occur. Low-grade fever is usually present. Anemia, if present, may reflect inability to utilize iron or impaired folic acid metabolism (see Chapters 446 and 447). Wound healing is slow, and apparently healed wounds often break down. Swollen joints and follicular hyperkeratosis are additional features, as is the sicca syndrome of Sjögren (xerostomia, keratoconjunctivitis sicca, and enlargement of the salivary glands [see Chapter 152]), which is usually associated with collagen disorders.

Diagnosis.

Laboratory tests for scurvy are unsatisfactory. Thus, diagnoses is usually based on the characteristic clinical picture, the radiographic appearance of the long bones, and a history of poor vitamin C intake.

The typical radiographic changes occur at the distal ends of the long bones. These are particularly common in the area of the knee. In the early stages of the condition, the appearance resembles that of simple bone atrophy. The trabeculae of the shaft cannot be discerned and the bone has a ground-glass appearance. The cortex is quite thin, and the epiphyseal ends of the bones are sharply outlined. The white line of Fraenkel, an irregular but thickened white line at the metaphysis, represents the zone of well-calcified cartilage. The epiphyseal centers of ossification also have a ground-glass appearance and are surrounded by a white ring (Fig. 44–5).

Scurvy cannot be diagnosed with certainty from the radiograph until a zone of rarefaction under the white line at the metaphysis becomes apparent. This zone of rarefaction is a linear break in the bone proximal and parallel to the white line. The lateral parts of the zone of rarefaction are seen as a triangular defect (see Fig. 44–5). A spur, or lateral prolongation of the

Figure 44-5 Radiographs of a leg. *A,* Early scurvy: "white line" is visible on the ends of the shafts of the tibia and fibula; rings are shown around the epiphyses of the femur and tibia. *B,* More advanced scorbutic changes; zones of destruction (ZD) are evident in the femur and tibia.

white line, may be present. Epiphyseal separation may occur along the line of destruction with either linear displacement or compression of the epiphysis against the shaft. Subperiosteal hemorrhages are not visible radiographically during the active phase of scurvy. During healing, however, the elevated periosteum becomes calcified and the affected bone assumes a dumbbell or club shape.

A fasting plasma vitamin C concentration of over 0.6?mg/dL aids in precluding vitamin C deficiency, but an even lower concentration does not necessarily indicate deficiency. The ascorbic acid concentration of the white cell/platelet layer (buffy layer) of centrifuged oxalated blood is a better indicator of vitamin C status. A level of zero in this layer indicates latent scurvy, even in the absence of clinical signs of deficiency. Saturation of the tissues with vitamin C can be estimated from the urinary excretion of the vitamin after a test dose of ascorbic acid. In normal children, 80% of the test dose appears in the urine within 3–5?hr after parenteral administration of the test dose. Generalized, nonspecific aminoaciduria is common in scurvy, but plasma amino acid concentrations remain normal. After a tyrosine load, scorbutic infants excrete metabolites similar to those of premature infants.

Scurvy is often misdiagnosed as arthritis or acrodynia. Copper deficiency also results in a radiographic picture that is very similar to that of scurvy. The pseudoparalysis of scurvy often is confused with that of syphilis; however, the latter usually occurs at an

earlier age than does that of scurvy and is usually accompanied by other signs of syphilis. Henoch-Schönlein purpura, thrombocytopenic purpura, leukemia, meningitis, or nephritis may also be suspected.

Prevention.

Scurvy can be prevented by an adequate intake of vitamin C. Citrus fruits and juices are excellent sources. Formula-fed infants usually receive adequate amounts of ascorbic acid, provided the formula is not heated excessively. Lactating mothers should consume about 100?mg of vitamin C daily. Older children and adults need somewhat more than infants (see Table 40–1).

Treatment.

Daily intake of 3–4?oz of orange juice or tomato juice quickly produces healing in children with scurvy, but ascorbic acid is preferable. The daily therapeutic dose is 100–200?mg, orally or parenterally. Recovery, including resumption of normal growth, is rapid with proper treatment. However, the swelling of subperiosteal hemorrhage may not disappear for months.

VITAMIN D

Two forms of vitamin D, vitamin D_2 and vitamin D_3 , are of practical importance. Both are produced synthetically and are available as dietary supplements. Vitamin D_3 also is naturally present in human skin; the provitamin form, 7-dehydrocholesterol, is activated photochemically to vitamin D_3 which is then transferred to the liver. Both vitamin D_2 and vitamin D_3 are hydroxylated in the liver to 25-OH-cholecalciferol and, subsequently, in the renal cortex to 1,25-dihydroxycholecalciferol, which functions as a hormone. Receptors for 1,25-dihydroxycholecalciferol are present in most tissues, but its primary roles are facilitation of intestinal absorption of calcium and phosphorus, renal reabsorption of phosphorus, and possibly a direct effect on bone deposition and reabsorption of calcium and phosphorus. With parathormone and calcitonin, 1,25-dihydroxycholecalciferol plays a major role in calcium and phosphorus homeostasis of both body fluids and body tissues.

The usual diet of infants contains only small amounts of vitamin D. Breast milk content is low, and bovine milk content is even lower. Cereals, vegetables, and fruits contain only negligible amounts. Most marketed cow's milk and infant formulas are fortified with vitamin D. Breast milk vitamin D probably is adequate if the infant is exposed sufficiently to sunlight. Dark-skinned infants who are not exposed adequately to sunlight should receive a supplement.

Children with steatorrhea (e.g., those with disorders such as celiac disease and cystic fibrosis) may become deficient secondary to deficient absorption of vitamin D. Anticonvulsant therapy with the phenytoins or phenobarbital may interfere with metabolism of vitamin D and, hence, increase the requirement. In addition, glucocorticoids appear to be antagonistic to vitamin D in calcium transport.

Vitamin D Deficiency

Vitamin D deficiency results in *rickets,* a term signifying failure to mineralize growing bone or osteoid tissue, or osteomalacia. The early changes of rickets are seen radiographically at the ends of long bones, but evidence of demineralization in the shafts also is present. Subsequently, if healing is not initiated, clinical manifestations appear (see later).

Epidemiology.

Formerly, the major cause of rickets in the United States was inadequate intake of vitamin D caused by inadequate direct exposure to sunlight, the rays of which do not pass through ordinary window glass, or inadequate vitamin D intake, or both. These are still important causes in developing countries. However, vitamin D deficiency rickets is now rare among infants and children in industrialized countries. Nevertheless, even in these latter countries, deficiency still occurs in unsupplemented dark-skinned infants, in breast-fed infants of mothers who are not exposed to sunlight, and in breast-fed infants who are not exposed to sunlight. There has been an increase in incidence of rickets in these populations of infants.

In industrialized countries, conditions other than inadequate vitamin D intake account for most of the observed cases of rickets (see Chapters 521.5 , 696 , 697 , and 698). These conditions include clinical entities that interfere with vitamin D absorption or metabolic conversion and activation, such as steatorrhea, hepatic and renal diseases, or conditions that disrupt calcium and phosphorus homeostasis in other ways.

Pathophysiology.

New bone formation is initiated by osteoblasts, which are responsible for matrix deposition and subsequent mineralization. Osteoblasts secrete collagen, and changes in polysaccharides, phospholipids, alkaline phosphatase, and pyrophosphatase follow until mineralization occurs. However, mineralization cannot occur unless adequate calcium and phosphorus are present. Resorption of bone occurs when osteoclasts secrete enzymes on the bone surface, which dissolve and remove both matrix and mineral. Osteocytes covered by bone both resorb and redeposit bone. The many factors that affect bone growth are poorly understood, but phosphorus, calcium, fluoride, and growth hormone are known to be involved.

In rickets, defective bone growth results from retardation or suppression of normal epiphyseal cartilage growth and calcification. These changes result from a deficiency of calcium and phosphorus salts in the serum. Cartilage cells fail to complete their normal cycle of proliferation and degeneration, with subsequent failure of capillary penetration, which occurs in a patchy manner. The result is a frayed, irregular epiphyseal line at the end of the shaft. Failure of osseous and cartilaginous matrix to mineralize in the zone of preparatory calcification, followed by deposition of newly formed uncalcified osteoid, results in a wide, irregular, frayed zone of nonrigid tissue (the rachitic metaphysis (Fig. 44–6). This zone is responsible for many of the skeletal deformities of rickets. It becomes compressed and bulges laterally, producing flaring of the ends of the bones and the rachitic rosary (Fig. 44–7). Mineralization is also lacking in subperiosteal bone. Pre-existing cortical bone is

resorbed in a normal manner, but it is replaced over the entire shaft by osteoid

---

Figure 44-6 Line tests in rats (proximal end of the tibia) (calcified tissue stained with silver appears black). *A,* Active rickets. The light broad zone between the epiphysis and the shaft represents the rachitic metaphysis (R.M.) C = cartilage; O = osteoid. *B,* Healing rickets. The line of preparatory calcification (L.P.C.) between the zone of cartilage (C) and the osteoid (O). *C,* Healed rickets. Cartilaginous disc (C) between the epiphysis and the normal shaft.

tissue that fails to mineralize. If this process continues, the shaft loses its rigidity and the softened and rarefied cortical bone is readily distorted by stress, resulting in deformities as well as fractures.

With healing, degeneration of cartilage cells along the metaphyseal-diaphyseal border occurs, capillary penetration of the resultant spaces is resumed, and calcification in the zone of preparatory calcification takes place. This calcification occurs approximately where normal calcification would have occurred had the rachitic process not supervened. It produces a line that is clearly visible on radiographs (Fig. 44–8). As healing progresses, the osteoid tissue between this line of preparatory calcification and the diaphysis also becomes mineralized, as does the osteoid tissue in the cortex and about the trabeculae in the shaft.

Figure 44-7 Rachitic rosary in a young infant.

Vitamin D–deficient rickets can be conceptualized as the body's attempt to maintain normal serum calcium levels. In the absence of vitamin D, less calcium is absorbed from the intestine and, with only a slight decrease in serum calcium concentration, parathormone is secreted. This, in turn, leads to mobilization of calcium and phosphorus from the bone. The serum calcium concentration is, thus, maintained, but secondary effects, including the changes of rickets in bone, a low serum phosphorus concentration (because parathormone decreases phosphorus reabsorption in the kidneys), and elevated serum phosphatase (due to increased osteoblastic activity), take place.

The alkaline phosphatase of serum, less than 200?IU/dL in normal children, increases to more than 500?IU/dL in mild rickets, and much higher levels are not uncommon. However, serum alkaline phosphatase levels may be normal in protein or zinc depleted infants with rickets.

Calcium and phosphorus homeostasis depends on the intestinal absorption of dietary calcium and phosphorus. Maximum calcium absorption occurs when the ratio of calcium to phosphorus in the diet is about 2:1; a lower ratio results in less calcium absorption. Calcium absorption is higher if the intestinal contents are acid and if the dietary sugar is lactose. Chelating agents, including the phytates of cereals, may decrease calcium absorption, and dietary iron may decrease phosphate absorption. High dietary levels of stearic and palmitic acids, which are poorly absorbed, also decrease calcium absorption.

Clinical Manifestations.

Craniotabes, one of the early clinical signs of rickets, is caused by thinning of the outer table of the skull. It can be detected by a Ping-Pong ball sensation when pressing firmly over the occiput or posterior parietal bones. Craniotabes near the suture lines is a normal variant. Nonrachitic craniotabes is sometimes present in normal infants during the immediate postnatal period but tends to disappear by the 2nd to 4th mo of life before rachitic softening of the skull would usually become manifest. Craniotabes also occurs in hydrocephalus and osteogenesis imperfecta, but these conditions are easily differentiated from rickets.

Palpable enlargement of the costochondral junctions (the rachitic rosary [see Fig. 44–7]) and thickening of the wrists and ankles (see Fig. 44–8) are other early clinical signs of osseous changes. Enlargement of the costochondral junctions occurs also in scurvy and chondrodystrophy. The enlargements with rickets are rounded knobs, whereas those with scurvy are a ledgelike depression, with the chondral or sternal portion displaced below the osseous ribs. Patients with chondrodystrophy may have irregular, concave outlines of the distal ends of the bones but no radiographic evidence of fraying. Other epiphyseal lesions that may require differentiation from rickets include congenital epiphyseal dysplasia, cytomegalic inclusion disease, syphilis, rubella, and copper deficiency.

Figure 44-8 *A,* Active rickets; cupping and fraying of the distal ends of the radius and ulna; double contour along the lateral outline of the radius (periosteal osteoid). The two dense zones in the shaft of the ulna are calluses of greenstick fractures. *B,* Healing rickets after 12 days of treatment with vitamin D. Zones of preparatory calcification (ZPC); above them in the rachitic metaphyses there is beginning calcification. *C,* Healing rickets after 18 days of treatment. The zones of preparatory calcification are well defined, and the rachitic metaphyses appear well calcified. The epiphysis of the radius has become visible. *D,* Healing rickets after 29 days of treatment. Zones of preparatory calcification, rachitic metaphyses, and shafts have become united.

Enlargement of the costochondral junctions may become prominent; the beading of the ribs is not only palpable but also visible (see Fig. 44–7). The sternum with its adjacent cartilage appears to project forward, the so-called pigeon breast deformity, and a horizontal depression, Harrison groove (Fig. 44–9), develops along the lower border of the chest. These deformities are often difficult to distinguish from congenital deformities.

The softness of the skull may result in flattening and, at times, permanent asymmetry of the head. The anterior fontanel is larger than normal, and its closure may be delayed until after the 2nd yr of life. The central parts of the parietal and frontal bones are often thickened, forming prominences, or bosses, and giving the head a boxlike appearance (caput quadratum). Eruption of the temporary teeth may be delayed, and there may be defects of the enamel and extensive caries. The permanent teeth that are calcifying during the period of vitamin D deficiency may also be affected; the permanent incisors, canines, and first molars almost always

have enamel defects.

Children with rickets frequently have a concomitant deformity of the pelvis, which is also retarded in growth. These changes in girls, if they become permanent, add to the hazards of childbirth and may necessitate cesarean section.

As the rachitic process continues, the epiphyseal enlargement at the wrists and ankles becomes more noticeable (see Fig. 44–8), and bending of the softened shafts of the femur, tibia, and fibula results in bowlegs or knock-knees. These are easily distinguishable from familial bow legs.

Greenstick fractures may occur in the long bones, often with no clinical symptoms. Deformities of the spine, pelvis, and legs result in reduced stature or rachitic dwarfism. Relaxation of ligaments contributes to production of the deformities, partly accounting for knock-knees, overextension of the knee joints, weak ankles, kyphosis, and scoliosis. The muscles are poorly developed and lack tone; as a result, children with moderately severe rickets do not stand or walk at the usual ages.

The osseous changes of rickets cannot be recognized radiographically until after several months of vitamin D deficiency. Breast-fed infants of vitamin D–deficient mothers may develop rickets within 2 mo, but rickets usually appears toward the end of the 1st and during the 2nd yr of life. Vitamin D–deficient rickets is rare later in childhood.

Diagnosis.

The serum calcium level of children with rickets may be normal or low, but the serum phosphorus level almost always is less than 4?mg/dL. The serum alkaline phosphatase level also is inevitably elevated, and the urinary cyclic AMP level is elevated. Serum 25-hydroxycholecalciferol is low.

Nonspecific findings of vitamin D deficiency include a generalized aminoaciduria, a low bone citrate level with elevated urinary citrate excretion, impaired renal acidification, phosphaturia, and, occasionally, glucosuria. The parathyroid glands hypertrophy in rickets, and urinary cyclic adenosine monophosphate level is increased.

The diagnosis of rickets is based on a history of inadequate intake of vitamin D or inadequate exposure to sunlight and the characteristic clinical signs of the condition. It is confirmed chemically and by radiographic examination.

Prevention.

Rickets can be prevented by exposure to ultraviolet light or by oral administration of vitamin D. Formula-fed infants and breast-fed infants of mothers who have adequate exposure to sunlight receive adequate intakes of vitamin D. This remains true after regular bovine milk (but not evaporated milk) replaces breast milk and/or formula.

Breast-fed infants whose mothers are not exposed to adequate sunlight, particularly those who also are protected from sunlight, dark-skinned infants, and infants born during the winter months in temperate climates also should receive a supplement of 400?IU of vitamin D daily, particularly if breast-fed.

Vitamin D should also be administered to pregnant and lactating mothers.

Treatment.

Both natural and artificial light of the appropriate wavelength are effective therapeutically, but oral administration of vitamin D is preferred. Daily administration of 50–150?µg of vitamin D_3 or 0.5–2?µg of 1,25-dihydroxycholecalciferol produces demonstrable radiographic healing within 2–4 wk, except in cases of vitamin D refractory rickets. Vitamin D_3 usually is adequate unless deficiency is secondary to hepatic or renal disease.

Figure 44-9 Deformities in rickets, showing the curvature of the limbs, potbelly, and Harrison groove.

A single dose of 15,000?µg of vitamin D without further therapy for several months may be advantageous. Healing is rapid, possibly allowing earlier differential diagnosis from genetic vitamin D–resistant rickets. If no healing occurs, the rickets is probably resistant to vitamin D (see Chapters 348.1 , 521.5 , and 696–698).

If sufficient amounts of vitamin D are administered, healing begins within a few days and progresses slowly until the normal bony structure is restored.

Rickets in itself is not a fatal disease, but complications and intercurrent infections are more likely to cause death of rachitic children than normal children.

Tetany of Vitamin D Deficiency (Infantile Tetany)

Tetany due to vitamin D deficiency occasionally accompanies rickets. This type of tetany has virtually disappeared with today's widespread prophylactic use of vitamin D. However, vitamin D deficiency tetany occurs, occasionally, in infants and children with severe steatorrhea, particularly if the serum ionized calcium concentration falls below 3–4?mg/dL. At this level, muscular irritability occurs, apparently due to the loss of the inhibitory control that calcium exerts on the neuromuscular junctions. See also Chapter 48 .

Diagnosis is based on the combined presence of rickets, low serum calcium concentration, and symptoms of tetany. The serum phosphorus and alkaline phosphatase levels are similar to those seen in rickets without tetany.

Hypervitaminosis D

Excessive amounts of vitamin D result in signs and symptoms similar to those of idiopathic hypercalcemia (see Chapter 693), which may be due to hypersensitivity to

vitamin D. Symptoms, which develop after 1–3 mo of excessive intake, include hypotonia, anorexia, irritability, constipation, polydipsia, polyuria, and pallor. Hypercalcemia and hypercalciuria are notable. Aortic valvular stenosis, vomiting, hypertension, retinopathy, and clouding of the cornea and conjunctiva may occur. Proteinuria may be present and, if excessive intake continues, renal damage and metastatic calcification occur. Radiographs of the long bones reveal metastatic calcification and generalized osteopetrosis.

Metastatic calcification occurs also in chronic nephritis, hyperparathyroidism, and idiopathic hypercalcemia. These conditions, particularly the latter two, also are accompanied by hypercalcemia.

Treatment includes discontinuing vitamin D intake and decreasing calcium intake. For severely affected infants, aluminum hydroxide can be given by mouth. Chelation therapy is rarely necessary.

VITAMIN E

Vitamin E (a-tocopherol) is a fat-soluble antioxidant that may be involved in nucleic acid metabolism, but its precise biochemical action is unclear. It is present in many foods (see Table 44–1).

Deficiency may occur in fat malabsorption states. Diets high in unsaturated fatty acids increase the vitamin E requirement in premature infants who absorb vitamin E poorly. Excess iron administration exaggerates signs of vitamin E deficiency.

Vitamin E Deficiency

Clinical Manifestations.

Some vitamin E–deficient individuals have creatinuria, ceroid deposition in smooth muscle, focal necrosis of striated muscle, and muscle weakness. Vitamin E deficiency also has been suggested as a causative factor in the anemia of kwashiorkor. Some premature infants with low serum levels of tocopherol develop hemolytic anemia between 6–10 wk of age that is correctable by administration of vitamin E. Platelet adhesiveness increases in deficiency states, as does the number of platelets. Vitamin E deficiency also has been suggested as a causative factor in retinopathy of prematurity, a possibility that is discussed more fully in Chapters 86 and 621 . Patients with malabsorption and vitamin E deficiency secondary to biliary atresia develop a degenerative, potentially reversible, neurologic syndrome consisting of cerebellar ataxia, peripheral neuropathy, and posterior column abnormalities.

Diagnosis.

Vitamin E deficiency is best detected by a serum ratio of a-tocopherol to lipid of less than 0.8?mg/g and/or erythrocyte hemolysis in hydrogen peroxide of more than 10%. Three days should elapse before determination of blood levels because orally administered vitamin E may circulate for 1–2 days. Thus, blood levels within 3 days of vitamin E administration may not reliably reflect vitamin E status.

Prevention and Treatment.

Minimal daily requirements of vitamin E are not known; 0.7?mg/g of unsaturated fat in the diet appears adequate. Children with deranged fat absorption should receive more. Premature infants may be given up to 15–25?IU per day. Large oral or parenteral doses of vitamin E may prevent permanent neurologic abnormalities in children with biliary atresia or abetalipoproteinemia.

VITAMIN K

Vitamin K is a naphthoquinone that participates in oxidative phosphorylation. Its absence or its failure to be absorbed from the intestinal tract results in hypoprothrombinemia and decreased hepatic synthesis of proconvertin, both of which are important to the second stage of coagulation (see Chapter 467). This stage of coagulation can be assessed by the one-stage prothrombin time (Quick). Administering vitamin K to a newborn infant increases concentrations of prothrombin, proconvertin, plasma thromboplastin component (factor IX), and Stuart-Prower factor (factor X). These four vitamin K–dependent proteins contain ?-carboxyglutamate and require calcium for activity. Other vitamin K–dependent proteins in plasma include proteins C, S, Z, and M. Factors C and S are anticoagulants. Factors Z and M stimulate platelet activity. Vitamin K–dependent calcium-binding proteins such as osteocalcin promote phospholipid interactions in coagulation and in calcium metabolism.

Naturally occurring vitamin K is fat soluble. It is designated vitamin K_1 to distinguish it from vitamin K_2 of bacterial origin and from synthetic naphthoquinones with vitamin K activity. The breast milk content of vitamin K is quite low. That of bovine milk is somewhat higher. The content of infant formulas is adequate. Vitamin K is present in high concentrations in liver, soybeans, and alfalfa and in smaller amounts in vegetables such as spinach, tomatoes, and kale.

190

Suppression of intestinal bacteria by antibiotics may be responsible for vitamin K deficiency. Irradiated foods have produced vitamin K deficiency in animals.

Vitamin K Deficiency

Clinical Manifestations.

Deficiency of vitamin K or hypoprothrombinemia should be considered in all patients with a hemorrhagic disturbance. The incidence of hemorrhagic disease of the newborn (see Chapter 92.4) has dropped sharply since prophylactic administration of vitamin K at birth became common. In childhood, vitamin K deficiency is usually caused by poor fat absorption or factors such as prolonged use of antibiotics that limit synthesis of the vitamin within the intestine. Diarrhea in infants, particularly breast-fed infants, may cause vitamin K deficiency. Diseases of the liver may limit

synthesis of prothrombin. Hypoprothrombinemia from this cause usually does not respond to administration of vitamin K.

Hypoprothrombinemia may also result from certain drugs. Dicumarol (or bishydroxycoumarin) is used specifically for the production of hypoprothrombinemia in the prevention and treatment of venous thrombosis. It is thought to prevent the liver from utilizing vitamin K rather than exerting a specific effect on prothrombin. Because blood prothrombin is continually destroyed in the body and dicumarol prevents its replacement, dicumarol treatment results in a decline in prothrombin. If a dangerously low level results, massive doses of vitamin K_1 may be necessary to restore prothrombin levels; whole blood transfusions also may be necessary.

Salicylic acid, a degradation product of dicumarol, produces hypoprothrombinemia by a similar mechanism. The reduction in prothrombin resulting from salicylates, however, is mild compared with that of dicumarol. The hemorrhagic manifestations of acute rheumatic fever may be caused in some cases by large doses of salicylates; this can be reversed by vitamin K administration. Thus, its use in children receiving large doses of salicylates appears justified.

Diagnosis.

Hypoprothrombinemia that is corrected by vitamin K administration establishes the diagnosis.

Prevention.

All infants should receive a prophylactic dose of vitamin K at birth. The breast-fed infant may benefit from additional vitamin K until the diet becomes more varied, but the formula-fed infant receives more than an adequate intake. Infants and children with prolonged diarrhea, as well as those who require prolonged antibiotic treatment or have steatorrhea, should receive supplemental vitamin K.

Treatment.

Oral administration of vitamin K may correct mild prothrombin deficiency. For an infant, 1–2?mg every 24?hr usually suffices. If prothrombin deficiency is severe and hemorrhagic manifestations have appeared, 5?mg of vitamin K_1 every 24?hr should be given parenterally. Large doses of synthetic vitamin K analogues, but not vitamin K_1 , may result in hyperbilirubinemia and kernicterus in newborns with glucose-6-phosphate dehydrogenase deficiency and in premature infants. Vitamin K can be given for hypoprothrombinemia secondary to liver damage, but whole blood is usually also necessary.

Part 7 - Pathophysiology of Body Fluids and Fluid Therapy

Larry A. Greenbaum

Chapter 45 - Electrolyte and Acid-Base Disorders

45.1 Composition of Body Fluids

Total Body Water.

Water is the most plentiful constituent of the human body. The other components of the body include protein, minerals, fat, and a small amount of carbohydrate. Total body water (TBW) as a percentage of body weight varies with age (Fig. 45–1). The fetus has a very high TBW, which gradually decreases to about 75% of birthweight for a term infant. Premature infants have a higher TBW content than term infants. During the 1st yr of life, TBW decreases to about 60% of body weight and basically remains at this level until puberty. At puberty, the fat content of girls increases more than boys, who acquire more muscle mass than girls. Because fat has very low water content and muscle has high water content, by the end of puberty TBW in boys remains at 60%, but TBW in girls decreases to about 50% of body weight. The high fat content in overweight children causes a decrease in TBW as a percentage of body weight. During dehydration the TBW decreases and, thus, is a smaller percentage of body weight.

Figure 45.1-1 Total body water, intracellular fluid, and extracellular fluid as a percentage of body weight and a function of age. (From Winters RW: Water and electrolyte regulation. In Winters RW [editor]: *The Body Fluids in Pediatrics.* Boston, Little, Brown & Company, 1973.)

Fluid Compartments.

TBW is divided between two main compartments: intracellular fluid (ICF) and extracellular fluid (ECF). In the fetus and newborn, the ECF volume is larger than the ICF volume (see Fig. 45–1). The postnatal diuresis causes an immediate decrease in the ECF volume. This is followed by continued expansion of the ICF volume, which results from cellular growth. By 1 yr of age the ratio of the ICF volume to the ECF volume approaches adult levels. The ECF volume is about 20–25% of body weight and the ICF volume is about 30–40% of body weight, close to twice the ECF volume (Fig. 45–2). With puberty, the increased muscle mass of boys causes them to have a higher ICF volume than girls. There is no significant difference in the ECF volume between postpubertal girls and boys.

The ECF is further divided into the plasma water and the interstitial fluid (see Fig. 45–2). The plasma water is normally about 5% of body weight. The blood volume, given a hematocrit of 40%, is usually close to 8% of body weight, although it is higher in newborns and young infants. In premature newborns it is around 10% of body weight. The volume of plasma water can be altered by a variety of pathologic conditions, including dehydration, anemia, polycythemia, heart failure, abnormal

Figure 45.1-2 Compartments of total body water, expressed as a percentage of body weight, in an older child or adult.

plasma osmolality, and hypoalbuminemia. The interstitial fluid, normally about 15% of body weight, can increase dramatically in diseases associated with edema such as heart failure, liver failure, nephrotic syndrome, and other causes of hypoalbuminemia. An increase in interstitial fluid occurs when patients develop ascites or pleural effusions.

There is normally a delicate equilibrium between the intravascular fluid and the interstitial fluid. The balance between hydrostatic and oncotic forces regulates the intravascular volume, which is critical for proper tissue perfusion. The intravascular fluid has a higher concentration of albumin than the interstitial fluid, and the consequent oncotic force draws water into the intravascular space. The maintenance of this gradient depends on the limited permeability of albumin across the capillaries. In contrast, the hydrostatic pressure of the intravascular space, which is due to the pumping action of the heart, drives fluid out of the intravascular space. In the capillaries these forces favor movement into the interstitial space at the arterial end of the capillaries. The decreased hydrostatic forces and increased oncotic forces, which result from the dilutional increase in albumin concentration, cause movement of fluid into the capillaries at the venous end of the capillaries. Overall, there is usually a net movement of fluid out of the intravascular space, but this fluid is returned to the circulation via the lymphatics. An imbalance in these forces may cause expansion of the interstitial volume at the expense of the intravascular volume. In children with hypoalbuminemia, the decreased oncotic pressure of the intravascular fluid contributes to the development of edema. Loss of fluid from the intravascular space may compromise the intravascular volume, placing the child at risk for inadequate blood flow to vital organs. This is especially likely in diseases with capillary leak because the loss of albumin from the intravascular space is associated with an increase in the albumin concentration in the interstitial space, further compromising the oncotic forces that normally maintain intravascular volume. In contrast, with heart failure, there is an increase in venous hydrostatic pressure from

expansion of the intravascular volume, which is caused by impaired pumping by the heart, and the increase in venous pressure causes fluid to move from the intravascular space to the interstitial space. Expansion of the intravascular volume and increased intravascular pressure also cause the edema that occurs with acute glomerulonephritis.

Electrolyte Composition.

The composition of the solutes in the ICF and ECF are very different (Fig. 45–3). Sodium and chloride are the dominant cations and anions, respectively, in the ECF. The sodium and chloride concentrations in the ICF are much lower. Potassium is the most abundant cation in the ICF, and its concentration within the cells is approximately 30 times higher than in the ECF. Proteins, organic anions, and phosphate are the most plentiful anions in the ICF. The dissimilarity between the anions in the ICF and the ECF is largely determined by the presence of intracellular molecules that do not cross the cell membrane, the barrier separating the ECF and the ICF. In contrast, the difference in the distribution of cations—sodium and potassium—is due to the activity of the Na^+ ,K^+ -ATPase, which uses cellular energy to extrude sodium from cells and move potassium into cells. The chemical gradient between the intracellular potassium concentration and extracellular potassium concentration creates the electrical gradient across the cell membrane. Specifically, the concentration-dependent movement of potassium out of the cell makes the intracellular space negative relative to the extracellular space.

The difference in the electrolyte compositions of the ECF and the ICF has important ramifications when evaluating and treating electrolyte disorders. The serum concentration of an electrolyte, which is measured clinically, does not always reflect the body content. This is due to the larger volume of the ICF compared with the ECF and the variation in electrolyte concentrations between these two compartments caused by intracellular processes. For example, the intracellular potassium concentration is much higher than the serum concentration. A shift of potassium from the intracellular potassium pool can maintain a normal or even an elevated serum potassium concentration, despite massive losses of potassium from the intracellular pool. This is dramatically seen in diabetic ketoacidosis, in which a state of significant potassium depletion is often masked because of a shift of potassium from the ICF to the ECF. For potassium and phosphorus, electrolytes with a high intracellular concentration, the serum level may not accurately reflect total body content. This may also be seen with the serum magnesium concentration.

Figure 45.1-3 The concentrations of the major cations and anions in the intracellular space and the plasma, expressed in mEq/L.

Similarly and more dramatically, the serum calcium concentration does not predict the body content of calcium, which is largely in bone.

Osmolality.

The ICF and the ECF are in osmotic equilibrium because the cell membrane is freely permeable to water. If the osmolality in one compartment changes, then water movement leads to a rapid equalization of osmolality. This can lead to significant shifts of water between the intracellular space and the extracellular space. Clinically, the primary process is usually a change in the osmolality of the ECF, with a resultant shift of water into the ICF if the ECF osmolality decreases or a shift of water out of the ICF if the ECF osmolality increases. The osmolality of the ECF can be determined, and this equals the ICF osmolality. The plasma osmolality is normally 285–295?mOsm/kg, and it is measured by the degree of freezing point depression. The plasma osmolality can also be calculated based on the following formula:

Glucose and blood urea nitrogen (BUN) are measured in mg/dL. Division by 18 and 2.8 converts the units into mmol/L. Multiplication of sodium by 2 accounts for its accompanying anions, principally chloride and bicarbonate. The calculated osmolality is usually slightly lower than the measured osmolality.

In most situations, glucose and urea contribute little to the plasma osmolality; multiplication of the sodium by 2 provides a rough approximation of the osmolality. In children with uremia, the urea concentration can have a significant impact on the plasma osmolality. However, urea is not confined to the extracellular space; it readily crosses cell membranes and its intracellular concentration approximately equals its extracellular concentration. Only substances that are confined to the extracellular space are osmotically active. Whereas an elevated sodium concentration causes a shift of water from the intracellular space, with uremia there is no osmolar gradient between the two compartments and consequently no movement of water. Urea is therefore considered an “ineffective osmole,” and hyperosmolality from uremia does not cause a fluid shift. The only exception is during hemodialysis, when the decrease in extracellular urea is so rapid that the intracellular urea does not have time to equilibrate. This may lead to the disequilibrium syndrome, in which water shifts into brain cells, potentially causing severe symptoms. Ethanol, because it freely crosses cell membranes, is another ineffective osmole. The effective osmolality can be calculated as follows:

The effective osmolality (also called the tonicity) determines the osmotic force that is mediating the shift of water between the ECF and the ICF.

Hyperglycemia causes an increase in the plasma osmolality and, unlike urea, glucose is an effective osmole because it is not in equilibrium with the intracellular space. During hyperglycemia there is a shift of water from the intracellular space to the extracellular space. This is clinically important in children with hyperglycemia during diabetic ketoacidosis. The shift of water causes dilution of the sodium in the extracellular space, causing hyponatremia despite an elevated plasma osmolality. The magnitude of this effect can be calculated as follows:

where $[Na]_{measured}$ equals the sodium concentration measured by the clinical laboratory and $[Na]_{corrected}$ equals the corrected sodium concentration (the sodium concentration if the glucose concentration were normal and its accompanying water moved back into the cells). The $[Na]_{corrected}$ is the more reliable indicator of the patient's true ratio of total body sodium to TBW, the normal determinant of the sodium concentration.

Normally the measured osmolality and the calculated osmolality are within 10?mOsm/kg. There are some clinical situations in which this does not occur. The presence of “unmeasured osmoles” causes the measured osmolality to be significantly elevated when compared with the calculated osmolality. This difference is the *osmolal gap*, which is present when the measured osmolality is more than 10?mOsm/kg greater than the calculated osmolality. Some examples of unmeasured osmoles include ethanol, ethylene glycol, methanol, and mannitol. These substances increase the measured osmolality, but are not part of the equation for calculating osmolality. The presence of an osmolal gap is a clinical clue to the presence of unmeasured osmoles and may be diagnostically useful when there is clinical suspicion of poisoning with methanol or ethylene glycol. A measured osmolality is necessary when monitoring the effect of mannitol therapy on plasma osmolality.

Pseudohyponatremia is a second situation in which there is discordance between the measured and calculated osmolality. Lipids and proteins are the solids of the serum. In patients with elevated serum lipids or proteins, the water content of the serum decreases because water is displaced by the increased amount of solids. Some clinical laboratories measure sodium concentration by determining the amount of sodium per liter of serum, including the solid component. When the solid component increases, there is a decrease in the sodium concentration per liter of serum, despite a normal concentration of sodium when based on the amount of sodium per liter of serum water. It is the concentration of sodium in serum water that is physiologically relevant. In such situations, the plasma osmolality is normal despite the presence of pseudohyponatremia because the method for measuring osmolality is not appreciably influenced by the percentage of serum that is composed of lipids and proteins. Pseudohyponatremia is diagnosed by finding a normal measured plasma osmolality despite hyponatremia. This laboratory artifact does not occur if the sodium concentration in water is measured directly with an ion-specific electrode, the technique that is increasingly used in clinical laboratories.

When there are no unmeasured osmoles and pseudohyponatremia is not a concern, the calculated osmolality provides an accurate estimate of the plasma osmolality. Measurement of plasma osmolality is useful for detecting or monitoring unmeasured osmoles and confirming the presence of true hyponatremia. Whereas many children with high plasma osmolality are dehydrated—as seen with hypernatremic dehydration or diabetic ketoacidosis—high osmolality does not always equate with dehydration. For example, a child with salt poisoning or uremia has an elevated plasma osmolality, but may be volume overloaded. In many situations it is best to focus on the components of the plasma osmolality and to analyze them individually to reach a correct clinical conclusion. The effective osmolality, which must be calculated, does provide useful information regarding the distribution of water between the ECF and ICF.

45.2 Regulation of Osmolality and Volume

Proper cell functioning requires close regulation of plasma osmolality and intravascular volume. These are controlled by independent systems for water balance, which determines osmolality, and sodium balance, which determines volume status. Maintenance of a normal osmolality depends on control of water balance. Although sodium concentration is the dominant determinant of plasma osmolality, the body does not control osmolality by regulating sodium balance. Normally, control of volume status depends on regulation of sodium balance. However, when volume

depletion is present, this takes precedence over regulation of osmolality, and retention of water contributes to maintenance of intravascular volume.

Regulation of Osmolality.

The plasma osmolality is tightly regulated to maintain it between 285 and 295?mOsm/kg. Modification of water intake and excretion maintains a normal plasma osmolality. In the steady state, water intake and water produced by the body from oxidation balances water losses from the skin, lungs, urine, and gastrointestinal tract. Only water intake and urinary losses can be regulated.

Osmoreceptors in the hypothalamus sense the plasma osmolality. It is only the effective osmolality that is sensed; this does not include solutes such as urea that readily diffuse across the cell membrane. An elevated effective osmolality leads to secretion of antidiuretic hormone (ADH) by neurons in the supraoptic and paraventricular nuclei in the hypothalamus. The axons of these neurons terminate in the posterior pituitary. Circulating ADH binds to its V_2 receptors in the collecting duct cells of the kidney, and, via the generation of cyclic adenosine monophosphate (cAMP), causes insertion of water channels (aquaporin-2) into the renal collecting ducts. This produces increased permeability to water, permitting reabsorption of water into the hypertonic renal medulla. The end result is that the urine concentration increases and water excretion decreases. Urinary water losses cannot be completely eliminated because there is obligatory excretion of urinary solutes, such as urea and sodium. The regulation of ADH secretion is tightly linked to plasma osmolality, with responses detectable with a 1% change in the osmolality. ADH secretion virtually disappears when the plasma osmolality is low, and this allows excretion of maximally dilute urine. The consequent loss of free water (water without sodium) corrects the plasma osmolality. ADH secretion is not an “all or nothing” response; there is a graded adjustment as the osmolality changes.

Production of concentrated urine under the control of ADH requires a hypertonic renal medulla. The counter current multiplier, produced by the loop of Henle and the vasa recta, generate this hypertonicity. ADH stimulates sodium transport in the loop of Henle, helping to maintain this gradient when water retention is necessary.

Water intake is regulated by hypothalamic osmoreceptors, though these are different from the osmoreceptors that determine ADH secretion. These osmoreceptors, by linking to the cerebral cortex, stimulate thirst when the serum osmolality increases. Thirst occurs with a small increase in the serum osmolality.

Control of osmolality is subordinate to maintenance of an adequate intravascular volume. When volume depletion is present, both ADH secretion and thirst are stimulated, regardless of the plasma osmolality. The sensation of thirst requires moderate volume depletion, but only a 1–2% change in the plasma osmolality. Although all of the mechanisms are not clear, angiotensin II, which is increased during volume depletion, is known to stimulate thirst. Baroreceptors, when sensing volume depletion, may also stimulate thirst.

A number of conditions can limit the kidney's ability to excrete adequate water to correct low plasma osmolality. In the syndrome of inappropriate antidiuretic hormone (SIADH), ADH continues to be produced despite a low plasma osmolality. In the presence of ADH, urinary dilution does not occur, and sufficient water is not excreted. A variety of diseases—mostly central nervous system, but also pulmonary and neoplastic—can cause SIADH (see Chapter 553). Iatrogenic excess of ADH is possible with the use of desmopressin acetate, a synthetic analog of ADH. Other medications, including narcotics, nicotine, cholinergics and barbiturates, stimulate ADH release. Although not as dramatic as SIADH, stress—such as pain, trauma, surgery, or burns—stimulates ADH release, preventing adequate water excretion and potentially causing hyponatremia.

The glomerular filtration rate (GFR) affects the kidney's ability to eliminate water. With a decrease in GFR, less water is delivered to the collecting duct, limiting the amount of water that can be excreted. The impairment in GFR must be quite significant to limit the kidney's ability to respond to an excess of water.

The minimum urine osmolality is approximately 30–50?mOsm/kg. This places an upper limit on the kidney's ability to excrete water; there must be sufficient solute present to permit water loss. Massive water intoxication may exceed this limit, whereas a lesser amount of water is necessary in the child with a diet that has very little solute. This is occasionally seen and can produce severe hyponatremia in children who receive little salt and have little urea production as a result of inadequate protein intake. Volume depletion is an extremely important cause of inadequate water loss by the kidney despite a low plasma osmolality. This “appropriate” secretion of ADH occurs because volume depletion takes precedence over the osmolality in the regulation of ADH.

The normal response to an increased plasma osmolality is conservation of water by the kidney. In central diabetes insipidus this does not occur because of an absence of ADH secretion (see Chapter 552). Ethanol produces a transient decrease in ADH production. Patients with nephrogenic diabetes insipidus (NDI) have an inability to

respond to ADH and produce dilute urine despite an increase in plasma osmolality. This is most dramatic in the inherited causes of NDI. X-linked NDI is due to an absence of the ADH receptor. The less common autosomal recessive form is secondary to a deficiency in aquaporin-2, the water channel that is necessary for retention of water by the collecting duct of the kidney. There is an extensive list of secondary causes of NDI, including medications such as lithium and kidney disorders such as renal dysplasia and acute tubular necrosis (see Chapter 522).

The maximum urine osmolality is about 1,200?mOsm/kg. The obligatory solute losses dictate the minimum volume of urine that must be produced, even when maximally concentrated. Obligatory water losses increase in patients with high salt intake or in patients with high urea losses, as may occur after relief of a urinary obstruction or during recovery from acute tubular necrosis. An increase in urinary solute and consequently water losses occurs with an osmotic diuresis, classically seen due to glucosuria in diabetes mellitus, and iatrogenically following mannitol administration. There are developmental changes in the kidney's ability to concentrate the urine. The maximum urine osmolality in a newborn, and especially a premature newborn, is less than in an older infant or child. This limits the ability to conserve water and makes these patients more vulnerable to hypernatremic dehydration. Very high fluid intake, as seen with psychogenic polydipsia, can dilute the high osmolality in the renal medulla, which is necessary for maximal urinary concentration. If fluid intake is restricted in these patients, there may be some impairment in the kidney's ability to concentrate the urine, although this defect corrects after a few days without polydipsia. This may also occur during the initial treatment of central diabetes insipidus with desmopressin acetate; the renal medulla takes time to achieve its normal maximum osmolality. Loop diuretics, such as furosemide, by inhibiting sodium reabsorption in the ascending limb of the loop of Henle, decrease medullary hypertonicity, preventing excretion of maximally concentrated urine.

Regulation of Volume.

An appropriate intravascular volume is critical for survival; both volume depletion and volume overload may cause significant morbidity and mortality. Because sodium is the principal extracellular cation and sodium is restricted to the ECF, adequate body sodium is necessary for maintenance of intravascular volume. The principal extracellular anion, chloride, is also necessary, but for simplicity, sodium balance is considered

the main regulator of volume status because body content of sodium and chloride usually changes proportionally given the need for equal numbers of cations and anions. In some situations, chloride depletion is considered the dominant derangement causing volume depletion (e.g., metabolic alkalosis with volume depletion). In other situations, such as volume depletion with metabolic acidosis, sodium depletion may exceed chloride depletion.

The kidney determines sodium balance because there is little homeostatic control of sodium intake, even though salt craving does occasionally occur, typically in children with chronic renal salt loss. The kidney regulates sodium balance by altering the percentage of filtered sodium that is reabsorbed along the nephron. Normally, the kidney excretes less than 1% of the sodium filtered at the glomerulus. In the absence of disease, extrarenal losses and urinary output match intake, with the kidney having the capacity to adapt to large variations in sodium intake. When necessary, urinary sodium excretion can be reduced to virtually undetectable levels or increased dramatically.

Urinary sodium excretion is regulated by both intrarenal and extrarenal mechanisms. The most important determinant of renal sodium excretion is the volume status of the child. More precisely, it is the *effective* intravascular volume that influences urinary sodium excretion. The effective intravascular volume is the volume status that is sensed by the body's regulatory mechanisms. For example, congestive heart failure is a state of volume overload, but the effective intravascular volume is low because poor cardiac function prevents adequate perfusion of the kidneys and other organs. This explains the avid renal sodium retention that is often present in such patients.

Sodium reabsorption occurs throughout the nephron (also see Chapter 520). Whereas the majority of filtered sodium is reabsorbed in the proximal tubule and the loop of Henle, the distal tubule and collecting duct are the main sites for precise regulation of sodium balance. Approximately 65% of the filtered sodium is reclaimed in the proximal tubule, which is the major site for reabsorption of bicarbonate, glucose, phosphate, amino acids, and other substances that are filtered by the glomerulus. The transport of all these substances is linked to sodium reabsorption by co-transporters or a sodium-hydrogen exchanger in the case of bicarbonate. This is clinically important for bicarbonate and phosphate because their reabsorption parallels sodium reabsorption. For example, in patients with metabolic alkalosis and volume depletion, correction of the metabolic alkalosis requires urinary loss of bicarbonate, but the volume depletion stimulates sodium and bicarbonate retention, preventing correction of the alkalosis. Similarly, volume expansion causes increased urinary losses of phosphate, even when there is phosphate depletion. In addition, reabsorption of uric acid and urea occurs in the proximal tubule and increases when sodium retention increases. This accounts for the elevated uric acid and BUN measurements that often accompany dehydration, which is a stimulus for sodium retention in the proximal tubule. The cells of the proximal tubule are permeable to water and thus water reabsorption in this segment parallels sodium reabsorption.

The loop of Henle is, in terms of absolute amount, the second most important site of sodium reabsorption along the nephron. The Na^+ ,K^+ ,$2Cl^-$ co-transporter on the luminal side of the membrane reclaims filtered sodium and chloride, while most of the potassium is recycled back into the lumen. This is the transporter that is inhibited by furosemide and other loop diuretics, which are highly effective at increasing sodium excretion. The ascending limb of the loop of Henle is not permeable to water, permitting sodium retention without water. ADH stimulates sodium retention in this segment; this helps to create a more hypertonic medulla, which maximizes water conservation when ADH acts in the medullary collecting duct. Because loop diuretics inhibit sodium retention in this segment, their use causes a less hypertonic medulla, and this prevents excretion of maximally concentrated urine in the presence of ADH.

Sodium retention in the distal tubule is mediated by the thiazide-sensitive Na^+ ,Cl^- co-transporter. This segment of the nephron is relatively impermeable to water and, along with sodium and chloride retention, the distal tubule is important for delivery of

fluid with a low sodium concentration to the collecting duct. This allows for excretion of water without sodium in patients who stop secreting ADH due to low plasma osmolality. Thiazide diuretics, by inhibiting sodium and chloride retention in this segment, prevent the excretion of water without electrolytes. This is a partial explanation for the severe hyponatremia that occasionally develops in patients on chronic thiazide diuretics.

The collecting duct, the final segment of the nephron, is important for regulation of excretion of water, potassium, acid, and sodium. Even though the amount of sodium reabsorbed in this segment is less than in any other segment, this is the critical site for the regulation of sodium balance. Sodium reabsorption occurs via a sodium channel that aldosterone regulates. When these channels are open under the influence of aldosterone, almost all of the sodium can be reabsorbed. The uptake of sodium creates a negative charge in the lumen of the collecting duct, which facilitates the secretion of potassium and hydrogen ions. The potassium-sparing diuretics amiloride and triamterene block these sodium channels, and the inhibition of sodium uptake decreases potassium excretion. In contrast, the potassium-sparing diuretic spironolactone blocks the binding of aldosterone to its receptor, and thus indirectly decreases the activity of the sodium channels. The collecting duct is important for regulation of water balance because it responds to ADH by inserting water channels that increase the permeability to water, and the hypertonicity of the renal medulla allows for maximal concentration of the urine.

Given the importance of sodium balance, it is not surprising that a number of systems are involved in the regulation of renal sodium excretion. The amount of sodium filtered at the glomerulus is directly proportional to the GFR. If sodium reabsorption in the nephron were constant, this would lead to complete reabsorption of sodium with a small decrease in the GFR and significant renal sodium wasting with a small increase. This does not occur, however, because sodium reabsorption in the nephron is proportional to sodium delivery, a principle called *glomerular tubular balance*.

The renin-angiotensin system is an important regulator of renal sodium excretion. The juxtaglomerular apparatus produces renin in response to decreased effective intravascular volume. Specific stimuli for renin release are decreased perfusion pressure in the afferent arteriole, decreased delivery of sodium to the distal nephron, and s1-adrenergic agonists, which increase during intravascular volume depletion. Renin, a proteolytic enzyme, cleaves angiotensinogen, producing angiotensin I. Angiotensin-converting enzyme (ACE) converts angiotensin I into angiotensin II. The actions of angiotensin II include direct stimulation of the proximal tubule to increase sodium reabsorption and stimulation of the adrenal gland to increase aldosterone secretion. Through its actions in the distal nephron, specifically the late distal convoluted tubule and the collecting duct, aldosterone increases sodium reabsorption. Aldosterone also stimulates potassium excretion, causing increased urinary losses. Along with decreasing urinary loss of sodium, angiotensin II is a vasoconstrictor, which helps to maintain an adequate blood pressure in the presence of volume depletion.

Volume expansion stimulates the synthesis of atrial natriuretic peptide (ANP), which is produced by the atria in response to distention. Along with increasing GFR, ANP inhibits sodium reabsorption in the medullary portion of the collecting duct, facilitating an increase in urinary sodium excretion.

Volume overload occurs when sodium intake exceeds output. In children with kidney failure there is an impaired ability to

excrete sodium. This tends to be proportional to the decrease in GFR, although in some kidney diseases, such as renal dysplasia or juvenile nephronophthisis, damaged tubules cause significant sodium loss until the GFR is almost zero. In general, as the GFR decreases, restriction of sodium intake becomes increasingly necessary. The GFR is low at birth, which limits a newborn's ability to excrete a sodium load. In other situations there is a loss of the appropriate regulation of renal sodium excretion. This occurs in patients with excessive aldosterone, as is seen in primary hyperaldosteronism or renal artery stenosis, wherein excess renin production leads to high aldosterone levels. In acute glomerulonephritis, even without a significantly reduced GFR, the normal intrarenal mechanisms that regulate sodium excretion malfunction, causing excessive renal retention of sodium and volume overload.

Renal retention of sodium occurs during volume depletion, but this appropriate response causes the severe excess in total body sodium that is present in congestive heart failure, liver failure, nephrotic syndrome, and other causes of hypoalbuminemia. In these diseases, the effective intravascular volume is decreased, causing the kidney and the various regulatory systems to respond, leading to renal sodium retention and edema formation.

Volume depletion usually occurs when losses of sodium exceed intake. The most common etiology in children is gastroenteritis. Along with the gastrointestinal tract, excessive losses of sodium may occur from the skin in children with burns, in sweat in patients with cystic fibrosis, or after vigorous exercise. Inadequate intake of sodium is uncommon except in neglect, famine, or with an inappropriate choice of liquid diet in a child who cannot take solids. Urinary sodium wasting may occur in a range of renal diseases, from renal dysplasia to tubular disorders such as Bartter syndrome. The neonate, especially if premature, has a mild impairment in the ability to conserve sodium. Iatrogenic renal sodium wasting takes place during diuretic therapy. Renal sodium loss occurs as a result of derangement in the normal regulatory systems. An absence of aldosterone, seen most commonly in children with congenital adrenal hyperplasia due to 21-hydroxylase deficiency, causes sodium wasting. In cerebral salt wasting, there may be a brain natruretic peptide that produces volume depletion secondary to renal sodium loss.

Isolated disorders of water balance can affect volume status and sodium balance. Because the cell membrane is permeable to water, changes in TBW influence both the extracellular volume and the intracellular volume. In isolated water loss, as occurs in diabetes insipidus, the impact is greater on the intracellular space because of its higher volume compared with the extracellular space. This is why, compared with other types of dehydration, hypernatremic dehydration has less impact on plasma volume; most of the fluid loss comes from the intracellular space. Yet, significant water loss does eventually affect intravascular volume and will stimulate

renal sodium retention, even if total body sodium content is normal. Similarly with acute water intoxication or SIADH, there is an excess of TBW, but most is in the intracellular space. However, there is some impact on the intravascular volume, and this causes renal excretion of sodium. Children with SIADH or water intoxication have high urine sodium concentrations despite hyponatremia. This reinforces the concept that there are independent control systems for water and sodium, yet the two systems interact when pathophysiologic processes dictate, and control of effective intravascular volume always takes precedence over control of osmolality.

45.3 Sodium

SODIUM METABOLISM

Body Content and Physiologic Function.

Sodium is the dominant cation of the ECF (see Fig. 45–3), and it is the principal determinant of extracellular osmolality. Sodium is therefore necessary for the maintenance of intravascular volume. Less than 3% of sodium is intracellular. More than 40% of total body sodium is in bone; the remainder is in the interstitial and intravascular spaces. The low intracellular sodium concentration, about 10?mEq/L, is maintained by Na^+ ,K^+ -ATPase, which exchanges intracellular sodium for extracellular potassium. The chemical gradient created by the high extracellular sodium concentration and the low intracellular sodium concentration provides the energy for the movement of a variety of substances into cells.

Intake.

A child's diet determines the amount of sodium ingested—a predominantly cultural determination in older children. An occasional child has salt craving due to an underlying salt-wasting disease. Children in the United States tend to have very high sodium intakes because their diets include a large amount of “junk food” and “fast food.” Infants receive sodium from breast milk (about 7?mEq/L) and formula (7–13?mEq/L for 20 calorie/oz formula).

Sodium is absorbed throughout the gastrointestinal tract, with limited regulation. Mineralocorticoids increase sodium transport into the body, although this has limited clinical significance. The presence of glucose enhances sodium absorption due to the presence of a co-transport system. This is the rationale for including sodium and glucose in oral rehydration solutions.

Excretion.

Sodium excretion occurs in stool and sweat, but the kidney regulates sodium balance and is normally the principal site of sodium excretion. There is some sodium loss in stool, but this is minimal unless diarrhea is present. Normally, sweat has 5–40?mEq/L of sodium. There is increased sweat sodium concentration in children with cystic fibrosis, aldosterone deficiency, or pseudohypoaldosteronism. The higher sweat losses in these conditions may cause or contribute to sodium depletion.

Sodium is unique among electrolytes because water balance, not sodium balance,

usually determines its concentration. Normally, when the sodium concentration increases, the resultant higher plasma osmolality causes increased thirst and increased secretion of ADH, which leads to renal conservation of water. Both of these mechanisms increase the water content of the body, and the sodium concentration returns to normal. During hyponatremia, the decrease in plasma osmolality stops ADH secretion, and consequent renal water excretion leads to an increase in the sodium concentration. Even though water balance is usually regulated by osmolality, volume depletion does stimulate thirst, ADH secretion, and renal conservation of water. In fact, volume depletion takes precedence over osmolality; volume depletion stimulates ADH secretion even if a patient has hyponatremia. This principle is critical for understanding the pathophysiology of many causes of hyponatremia.

The excretion of sodium by the kidney is *not* regulated by the plasma osmolality. The patient's effective plasma volume determines the amount of sodium in the urine. This is mediated by a variety of regulatory systems, including the renin-angiotensin-aldosterone system and intrarenal mechanisms. In hyponatremia or hypernatremia, the underlying pathophysiology determines the amount of urinary sodium, not the serum sodium concentration.

HYPERNATREMIA

Hypernatremia is a sodium concentration greater than 145?mEq/L, although it is sometimes defined as greater than 150?mEq/L. Mild hypernatremia is fairly common in children, especially among infants with gastroenteritis. Hypernatremia in hospitalized patients is frequently iatrogenic, caused by inadequate water administration or excessive sodium administration. Moderate or severe hypernatremia has significant morbidity, the result of underlying disease, the effects of hypernatremia on the brain, and the risks of overly rapid correction.

Etiology and Pathophysiology.

There are three basic mechanisms of hypernatremia (Box 45–1). Sodium intoxication is frequently iatrogenic in a hospital setting as a result of correction of metabolic acidosis with sodium bicarbonate. Baking soda, a putative remedy for upset stomach, is another source of sodium bicarbonate; the hypernatremia is accompanied by a profound metabolic alkalosis. In hyperaldosteronism, there is excessive renal retention of sodium.

The classic causes of hypernatremia from a water deficit are nephrogenic and central diabetes insipidus (see Chapters 522 and 552). Hypernatremia in diabetes insipidus only develops if the patient does not have access to water or cannot drink adequately because of neurologic impairment, emesis, or anorexia. Infants are at high risk because of their inability to control their own water intake. Central diabetes insipidus and the genetic forms of nephrogenic diabetes insipidus typically cause massive urinary water losses and very dilute urine. In contrast, the water losses are less dramatic and the urine often has the same osmolality as plasma when nephrogenic diabetes insipidus is secondary to diseases such as obstructive uropathy, renal dysplasia, or sickle cell disease. The other causes of a water deficit are also secondary to an imbalance between losses and intake. Newborns, especially if premature, have high insensible water losses. Losses are further increased under a radiant warmer or if the baby is receiving phototherapy for hyperbilirubinemia. The renal concentrating mechanisms are not optimal at birth, providing an additional source of water loss. Ineffective breast-feeding, often in a primipara, can cause severe hypernatremic dehydration. Adipsia, the absence of thirst, is usually secondary to damage to

Box 45.3-1. Causes of Hypernatremia

EXCESSIVE SODIUM

- Improperly mixed formula
- Excess sodium bicarbonate
- Ingestion of seawater or sodium chloride
- Intentional salt poisoning (child abuse or Münchhausen syndrome by proxy)

the hypothalamus, such as from trauma, tumor, hydrocephalus, or histiocytosis. Primary adipsia is rare.

When hypernatremia occurs in conditions with deficits of sodium and water, the water deficit exceeds the sodium deficit. This only occurs if the patient is unable to ingest adequate water. Diarrhea results in both sodium and water depletion. Because diarrhea is hypotonic—typical sodium concentration of 35–65?mEq/L—water losses are in excess of sodium losses, potentially leading to hypernatremia. Most children with gastroenteritis do not develop hypernatremia because they drink enough hypotonic fluid to compensate for stool water losses. Fluids such as water, juice, and formula are more hypotonic than the stool losses, allowing correction of the water deficit, and potentially even causing hyponatremia. Hypernatremia is most likely in the child with diarrhea who has inadequate intake, either due to emesis, lack of access to water, or anorexia.

Osmotic agents, including mannitol or glucose in diabetes mellitus, lead to excessive renal losses of water and sodium. Because the urine is hypotonic—sodium concentration of about 50?mEq/L—during an osmotic diuresis, water loss exceeds sodium loss, and hypernatremia may occur if water intake is inadequate. Certain chronic kidney diseases, such as renal dysplasia and obstructive uropathy, are associated with tubular dysfunction, leading to excessive losses of water and sodium. Many such children have disproportionate water loss and are at risk for hypernatremic dehydration, especially if gastroenteritis supervenes. Similar mechanisms occur during the polyuric phase of acute tubular necrosis and following relief of urinary obstruction (postobstructive diuresis). These patients may have an osmotic diuresis from urinary losses of urea and an inability to conserve water because of tubular dysfunction.

Clinical Manifestations.

Most children with hypernatremia are dehydrated and have the typical signs and symptoms of dehydration (see Chapter 47). Children with hypernatremic dehydration tend to have better preservation of intravascular volume because of the shift of water from the intracellular space to the extracellular space. This maintains blood pressure and urine output, and allows hypernatremic infants to be less symptomatic initially and potentially become more dehydrated before seeking medical attention. Breast-fed infants with hypernatremia are often profoundly dehydrated. Probably because of intracellular water loss, the pinched abdominal skin of a dehydrated, hypernatremic infant has a “doughy” feel.

Hypernatremia, even without dehydration, causes central nervous system symptoms that tend to parallel the degree of sodium elevation and the acuity of the increase. Patients are irritable, restless, weak, and lethargic. Some infants have a high-pitched cry and hyperpnea. Alert patients are very thirsty, even though nausea may be present. Hypernatremia causes fever, although many patients have an underlying process that contributes to the fever. Hypernatremia is associated with hyperglycemia and mild hypocalcemia; the mechanisms are unknown. Beyond the sequelae of dehydration, there is no clear direct effect of hypernatremia on other organs or tissues except the brain.

Brain hemorrhage is the most devastating consequence of hypernatremia. As the extracellular osmolality increases, water moves out of brain cells, resulting in a decrease in brain volume. This can result in tearing of intracerebral veins and bridging blood vessels as the brain moves away from the skull and the meninges. Patients may have subarachnoid, subdural, and parenchymal hemorrhage. Seizures and coma are possible sequelae of the hemorrhage, even though seizures are more common during treatment. The cerebral spinal fluid protein is often elevated in infants with significant hypernatremia, probably due to leakage from damaged blood vessels. Neonates, especially if premature, seem especially vulnerable to hypernatremia and excessive sodium intake. There is an association between

rapid or hyperosmolar sodium bicarbonate administration and development of intraventricular hemorrhages in neonates. Even though central pontine myelinolysis (CPM) is classically associated with overly rapid correction of hyponatremia, both CPM and extrapontine myelinolysis can occur in children with hypernatremia. Thrombotic complications occur in severe hypernatremic dehydration and include stroke, dural sinus thrombosis, peripheral thrombosis, and renal vein thrombosis. This is secondary to dehydration and possibly hypercoagulability associated with hypernatremia.

Diagnosis.

The etiology of hypernatremia is usually apparent from the history. Hypernatremia resulting from water loss only occurs if the patient does not have access to water or is unable to drink. In the absence of dehydration, it is important to ask about sodium intake. Children with excess sodium intake do not have signs of dehydration, unless another process is present. Severe sodium intoxication causes signs of volume overload such as pulmonary edema. In hyperaldosteronism, hypernatremia is usually mild or absent and is associated with hypertension, hypokalemia, and metabolic alkalosis.

When there is isolated water loss, the signs of volume depletion are usually less severe initially because much of the loss is from the intracellular space. When pure water loss causes signs of dehydration, the hypernatremia and water deficit are usually severe. In the child with renal water loss, either central or nephrogenic diabetes insipidus, the urine is inappropriately dilute and urine volume is not low. The urine is maximally concentrated and urine volume is low if the losses are extrarenal or due to inadequate intake. With extrarenal losses of water, the urine osmolality should be greater than 1,000?mOsm/kg. When diabetes insipidus is suspected, the evaluation may include measurement of ADH and a water deprivation test, including a trial of desmopressin acetate (synthetic ADH analog) to differentiate nephrogenic and central diabetes insipidus (see Chapters 522 and 552). A water deprivation test is unnecessary if the patient has simultaneous documentation of hypernatremia and poorly concentrated urine (osmolality less than plasma). In children with central diabetes insipidus, administration of desmopressin acetate increases the urine osmolality above the plasma osmolality, even though maximum osmolality does not occur immediately because of the decreased osmolality of the renal medulla from the chronic lack of ADH. In children with central diabetes insipidus, urine is concentrated when desmopressin acetate is given, but in children with nephrogenic diabetes insipidus, there is no such response.

With combined sodium and water deficits, analysis of the urine differentiates renal and nonrenal etiologies. When the losses are extrarenal, the kidney responds to volume depletion with low urine volume, a concentrated urine, and sodium retention (urine sodium less than 20?mEq/L). With renal causes, the urine volume is not appropriately low, the urine is not maximally concentrated, and the urine sodium may be inappropriately elevated.

Treatment.

As hypernatremia develops, the brain generates idiogenic osmoles to increase the intracellular osmolality and prevent the loss of brain water. This mechanism is not instantaneous and is most prominent when hypernatremia has developed gradually. If the serum sodium concentration is lowered rapidly, there is movement of water from the serum into the brain cells to equalize the osmolality in the two compartments (Fig. 45–4). The resultant brain swelling is clinically similar to the consequences of acute hyponatremia and most commonly manifests as seizures in infants.

Because of the dangers of overly rapid correction, hypernatremia should not be corrected rapidly. The goal is to decrease the serum sodium by less than 12?mEq/L every 24?hr, a rate of 0.5?mEq/L/hr. The most important component of correcting moderate or severe hypernatremia is frequent monitoring of the

Figure 45.3-4 Mechanism of brain edema during correction of hypernatremia. A rapid decrease of the serum concentration during treatment of hypernatremia causes movement of water into brain cells, leading to cerebral edema. The presence of idiogenic osmoles in brain cells is responsible for the osmotic gradient.

serum sodium so that fluid therapy can be adjusted to provide adequate correction, neither too slow nor too fast. If a child develops seizures from brain edema secondary to overly rapid correction, administration of hypotonic fluid should be stopped and an infusion of 3% saline can acutely increase the serum sodium, reversing the cerebral edema. This is similar to the approach for correcting symptomatic hyponatremia.

In the child with hypernatremic dehydration, as in any child with dehydration, the first priority is restoration of intravascular volume with isotonic fluid (see Chapter 46). Normal saline is preferable to lactated Ringer solution because the lower sodium concentration of the lactated Ringer solution can cause the serum sodium to decrease too rapidly, especially if multiple fluid boluses are given.

The sodium concentration of the fluid, the rate of fluid administration, and the presence of continued water losses determine the rate of decrease of the sodium concentration. The following formula is often cited for calculating the water deficit:

This is equivalent to between 3 and 4?mL of water per kilogram for each 1?mEq that

the current sodium is greater than 145. The utility of such formulas has never been proven in clinical practice. Most patients with hypernatremic dehydration do well with a fluid sodium concentration between 1/4 NS and 1/2 NS, but with a fluid rate that is only 20–50% greater than maintenance. This prevents excessive delivery of free water and too rapid a decrease in the serum sodium. Excessive water and sodium losses may also need to be replaced. If signs or symptoms of volume depletion develop, the patient receives additional boluses of isotonic saline. Monitoring of the rate of decrease of the serum sodium concentration permits adjustment in the rate and sodium concentration of the fluid that the patient is receiving, avoiding overly rapid correction of the hypernatremia.

Acute, severe hypernatremia, usually secondary to sodium administration, can be corrected more rapidly because idiogenic osmoles have not had time to accumulate. This balances the high morbidity and mortality from hypernatremia with the dangers of overly rapid correction. When hypernatremia is due to sodium intoxication and the hypernatremia is severe, it may be impossible to administer enough water to rapidly correct the hypernatremia without worsening volume overload. In this situation,

peritoneal dialysis allows for removal of the excess sodium. This requires dialysis fluid with a high glucose concentration and a low sodium concentration. In less severe cases, the addition of a loop diuretic increases removal of excess sodium and water, decreasing the risk of volume overload. With sodium overload, hypernatremia is corrected with sodium-free intravenous fluid (e.g., D5W).

Hyperglycemia from hypernatremia is not usually treated with insulin because the acute decrease in glucose, by lowering plasma osmolality, may precipitate cerebral edema. Rather, the glucose concentration of intravenous fluids should be reduced (e.g., change from D5 to D2.5). The secondary hypocalcemia is treated as needed.

It is important, if possible, to address the underlying cause of the hypernatremia. The child with central diabetes insipidus should receive desmopressin acetate. Since this reduces renal excretion of water, excessive intake of water must consequently be avoided to prevent overly rapid correction of the hypernatremia or the development of hyponatremia. Long term, reduced sodium intake and medications can somewhat ameliorate the water losses in nephrogenic diabetes insipidus (see Chapter 522). The daily water intake of a child who is on tube feeding may need to be increased to compensate for high losses. The patient with significant ongoing losses such as diarrhea may need supplemental water and electrolytes (see Chapter 46). Sodium intake is reduced if this contributed to the hypernatremia.

HYPONATREMIA

Hyponatremia, a very common electrolyte abnormality in hospitalized patients, is a serum sodium level below 135?mEq/L. Both total body sodium and TBW determine the serum sodium concentration. Hyponatremia exists when the ratio of water to sodium is increased. This can occur with low, normal, and high levels of body sodium. Similarly, body water can be low, normal, or high.

Etiology and Pathophysiolgy.

The causes of hyponatremia are listed in Box 45–2 . Pseudohyponatremia is a laboratory artifact that is present when the plasma contains very high concentrations of protein or lipid. It does not occur if a direct ion-selective electrode determines the sodium concentration, a technique that is increasingly used in clinical laboratories. In true hyponatremia, the measured osmolality is low, whereas it is normal in pseudohyponatremia. Hyperosmolality due to mannitol or glucose causes a low serum sodium concentration because water moves down its osmotic gradient from the intracellular space into the extracellular space, diluting the sodium concentration. However, because the manifestations of hyponatremia are due to the low plasma osmolality, patients with hyponatremia resulting from hyperosmolality do not have symptoms of hyponatremia. When the etiology of the hyperosmolality resolves, such as hyperglycemia in diabetes mellitus, water moves back into the cells and the sodium concentration increases to its “true” value.

The classification of hyponatremia uses the patient's volume status. The hypovolemic child with hyponatremia has lost sodium from the body. Water balance may be positive or negative, but there has been a higher proportion of sodium loss than water loss. The pathogenesis of the hyponatremia is usually due to a combination of sodium loss and water retention to compensate for the volume depletion. The patient has a pathologic increase in fluid loss, and this fluid contains sodium. However, most fluid that is lost has a lower sodium concentration than plasma so would actually cause hypernatremia if the patient only has fluid loss. For example, viral diarrhea has, on average, a sodium concentration of 50?mEq/L. Hypernatremia does not occur because the patient drinks a low sodium–containing fluid such as formula or water. By replacing diarrheal fluid, which has a sodium concentration of 50?mEq/L, with formula, which has

†Most cases of proximal renal tubular acidosis are not due to this primary genetic disorder. Proximal RTA is usually part of Fanconi syndrome, which has multiple etiologies (see Chapter 521 .)

only about 10?mEq/L of sodium, there is a reduction in the sodium concentration. Intravascular volume depletion interferes with renal water excretion, the body's usual mechanism for preventing hyponatremia. The volume depletion stimulates ADH synthesis, resulting in renal water retention in the collecting duct. In addition, volume depletion decreases the GFR and enhances water reabsorption in the proximal tubule, which reduces water delivery to the collecting duct.

Diarrhea due to gastroenteritis is the most common cause of hypovolemic hyponatremia in children. Emesis causes hyponatremia if the patient takes in hypotonic fluid, either intravenously or enterally, despite the emesis. However, most patients with emesis have either a normal sodium concentration or hypernatremia. Burns may cause massive losses of an isotonic fluid and volume depletion. Hyponatremia develops if the patient receives hypotonic fluid. Losses of sodium from sweat are especially high in children with cystic fibrosis, aldosterone deficiency, or pseudohypoaldosteronism, although high losses

can occur simply due to a hot climate. Third space losses are isotonic and can cause significant volume depletion, leading to ADH production and water retention, which can cause hyponatremia if the patient receives hypotonic fluid. In diseases with volume depletion due to extrarenal sodium loss, the urine sodium should be low (<10?mEq/L) as part of the renal response to maintain the intravascular volume. The only exceptions are diseases with both extrarenal sodium losses and renal losses: adrenal insufficiency and pseudohypoaldosteronism.

Renal sodium loss may occur in a variety of situations. In some situations, the urine sodium concentration is higher than 140?mEq/L, and, thus, hyponatremia may occur without any fluid intake. In many cases, the urine sodium is less than the serum concentration, and thus the intake of hypotonic fluid is necessary for hyponatremia to develop. In diseases with urinary sodium loss, the urine sodium is more than 20?mEq/L despite volume depletion. This may not be true if the urinary sodium loss is no longer occurring, as is frequently the case if diuretics are stopped. Because loop diuretics prevent generation of a maximally hypertonic renal medulla, patients can neither maximally dilute nor concentrate the urine. The inability to maximally retain water provides some protection against severe hyponatremia. Patients receiving thiazide diuretics can concentrate the urine and are at higher risk for severe hyponatremia. Osmotic diuretics, such as glucose during diabetic ketoacidosis, cause loss of both water and sodium. Urea accumulates during renal failure and then acts as an osmotic diuretic after relief of urinary tract obstruction and during the polyuric phase of acute tubular necrosis. Transient tubular damage in these conditions further impairs sodium conservation. The serum sodium concentration in these conditions is dependent on the sodium concentration of the fluid used to replace the losses. Hyponatremia develops when the fluid is hypotonic relative to the urinary losses.

Renal salt wasting occurs in hereditary kidney diseases such as juvenile nephronophthisis and autosomal recessive polycystic kidney disease. Obstructive uropathy, most commonly a consequence of posterior urethral valves, produces salt wasting, but these patients may also develop hypernatremia due to impaired urinary concentrating ability and high water loss. Acquired tubulointerstitial nephritis, usually secondary to either medications or infections, may cause salt wasting, along with other evidence of tubular dysfunction. Central nervous system injury may produce cerebral salt wasting, which appears to be mediated by production of a natriuretic peptide that causes renal salt wasting (see Chapter 553.2). In type II renal tubular acidosis (RTA), usually associated with Fanconi syndrome, there is increased excretion of sodium and bicarbonate in the urine. Patients with Fanconi syndrome also have glycosuria, aminoaciduria, and hypophosphatemia due to renal phosphate wasting.

Aldosterone is necessary for renal sodium retention and for excretion of potassium and acid. In congenital adrenal hyperplasia due to 21-hydroxylase deficiency, the absence of aldosterone produces hyponatremia, hyperkalemia, and metabolic acidosis. In pseudohypoaldosteronism, aldosterone levels are elevated, but there is no response because of either a defective sodium channel or a lack of aldosterone receptors. A lack of tubular response to aldosterone may occur in children with urinary tract obstruction, especially during an acute urinary tract infection.

In hypervolemic hyponatremia, there is an excess of TBW and sodium, although the increase in water is greater than the increase in sodium. The pathogenesis of hypervolemic hyponatremia is somewhat similar to hypovolemic hyponatremia. In most of the conditions that cause hypervolemic hyponatremia, there is a decrease in the effective blood volume, due to either third spacing of fluid or poor cardiac function. The regulatory systems of the body sense this decrease and attempt to retain water and sodium in order to correct the problem. ADH causes renal water retention and the kidney, under the influence of aldosterone and other intrarenal mechanisms, retains sodium. The patient's sodium concentration decreases because water intake exceeds sodium intake, and ADH prevents the normal loss of excess water.

In these disorders, there is a low urine sodium concentration (<10?mEq/L) and an excess of both water and sodium. The only exception is the patient with renal failure and hyponatremia. These patients have an expanded intravascular volume, and hyponatremia can therefore appropriately suppress ADH production. Water cannot be excreted because very little urine is being made. Serum sodium is diluted by ingesting water. Because of renal dysfunction, urine sodium concentration may be

elevated, but urine volume is so low that patients have not kept up with their sodium intake and therefore are also sodium overloaded. The urine sodium concentration in renal failure varies. In acute glomerulonephritis, because it does not affect the tubules, the urine sodium is usually low, whereas in patients with acute tubular necrosis, the urine sodium is elevated due to tubular dysfunction.

Patients with hyponatremia and no evidence of volume overload or volume depletion have euvolemic hyponatremia. These patients typically have an excess of TBW and a slight decrease in total body sodium. Some of these patients have an increase in weight, implying that they are technically overloaded. Nevertheless, from a clinical standpoint they usually appear normal or have subtle signs of fluid overload.

In SIADH, there is secretion of ADH that is not inhibited by either low serum osmolality or expanded intravascular volume (see Chapter 553.1). The result is that the child with SIADH is unable to excrete water. This results in dilution of the serum sodium and hyponatremia. In addition, the expansion of the extracellular volume due to the retained water causes a mild increase in intravascular volume. The kidney increases sodium excretion in an effort to decrease intravascular volume to normal and, thus, these patients have a mild decrease in body sodium. SIADH most commonly occurs with central nervous system pathology, but lung disease and tumors are other potential causes. In addition, a variety of medications may cause SIADH. The diagnosis of SIADH is one of exclusion, because other causes of hyponatremia must be eliminated (Box 45–3). Because SIADH is a state of intravascular volume expansion, low serum uric acid and BUN levels are supportive of the diagnosis.

Hyponatremia in the hospital frequently occurs in children who inappropriately produce ADH as a result of stress and who receive hypotonic intravenous fluids. The synthetic analog of ADH, desmopressin acetate, causes water retention and may cause hyponatremia if fluid intake is not appropriately limited. The main uses of desmopressin acetate in children are for the management of central diabetes insipidus and nocturnal enuresis.

Excess water ingestion can produce hyponatremia. In these cases, the sodium concentration decreases as a result of dilution. This suppresses ADH secretion and there is a marked water diuresis by the kidney. Hyponatremia only develops because the

Box 45.3-3. Diagnostic Criteria for Syndrome of Inappropriate Antidiuretic Hormone

Absence of:

- Congestive heart failure, nephrotic syndrome, or cirrhosis
- Diuretic ingestion
- Dehydration
- Urine osmolality > 100 (usually > plasma)
- Serum osmolality < 280 and serum sodium < 135
- Urine sodium > 25

intake of water exceeds the kidney's ability to eliminate water. This is more likely to occur in infants because their lower GFR limits their ability to excrete water. In some situations, the water intoxication causes acute hyponatremia and is due to a massive acute water load. Examples include infant swimming lessons, inappropriate hypotonic intravenous fluids, water enemas, and forced water intake as a form of child abuse. Chronic hyponatremia occurs in children who receive water, but limited sodium and protein. The minimum urine osmolality is approximately 50?mOsm/kg so the kidney can only excrete a liter of water if there is enough solute ingested to produce 50?mOsm for urinary excretion. Because sodium and urea—a breakdown product of protein—are the principal urinary solutes, a lack of sodium and protein intake prevents adequate water excretion. This occurs with diluted formula or other inappropriate diets. Subsistence on beer, a poor source of sodium and protein, causes hyponatremia resulting from the inability to excrete the high water load ("beer potomania").

The pathogenesis of the hyponatremia in glucocorticoid deficiency or hypothyroidism is incompletely understood. There is an inappropriate retention of water by the kidney, but the precise mechanisms are not clearly elucidated.

Clinical Manifestations.

Hyponatremia causes a decrease in the osmolality of the extracellular space. Because the intracellular space then has a higher osmolality, water inevitably moves from the extracellular space to the intracellular space to maintain osmotic equilibrium. The increase in intracellular water causes cells to swell. Cell swelling is not problematic in most tissues of the body. It is, however, potentially catastrophic in the brain. This is because the brain is contained in a fixed shell, the skull. As brain cells swell, there is an increase in intracranial pressure. Acute, severe hyponatremia can cause brainstem herniation and apnea; respiratory support is often necessary. Brain cell swelling is responsible for most of the symptoms of hyponatremia. Neurologic symptoms of hyponatremia include anorexia, nausea, emesis, malaise, lethargy, confusion, agitation, headache, seizures, coma, and decreased reflexes. Patients may develop hypothermia and Cheyne-Stokes respirations. Hyponatremia can cause muscle cramps and weakness.

The symptoms of hyponatremia are mostly due to the decrease in extracellular osmolality and the resulting movement of water down its osmotic gradient into the intracellular space. However, brain swelling can be significantly obviated if the hyponatremia develops gradually. This is because the brain adapts to the decreased extracellular osmolality by decreasing its internal osmolality. Initially, this is mostly through loss of sodium, potassium, and chloride. More chronically there is loss of intracellular osmoles such as amino acids, which accounts for why the degree of symptoms in hyponatremia is related to both the serum sodium level and its rate of decrease. A patient with chronic hyponatremia may be asymptomatic with a level of 110?mEq/L, but another patient may have seizures due to an acute decline from 140 to 125?mEq/L.

Patients with hyponatremic dehydration have more manifestations of intravascular volume depletion than patients who have equivalent water loss but normal or increased sodium concentrations. During hyponatremia, there is movement of water into the cells, which depletes the water of the extracellular space, including the plasma volume.

Diagnosis.

The history usually points to a likely etiology of the hyponatremia. Most patients with hyponatremia have a history of volume depletion. Diarrhea and diuretic use are very common etiologies of hyponatremia in children. A history of polyuria, perhaps with enuresis, and/or salt craving is present in children with primary kidney diseases or absence of aldosterone effect. Children may have signs or symptoms supportive of a diagnosis of hypothyroidism or adrenal insufficiency (see Chapters 559 and 569). Brain injury raises the possibility of SIADH or cerebral salt wasting. Liver disease, nephrotic syndrome, renal failure, or congestive heart failure may be acute or chronic. The history should include a review of the patient's intake, both intravenous and enteral, with careful attention to water, sodium, and protein amounts.

The traditional first step in the diagnostic process is the determination of the plasma osmolality. This is done because some patients with a low serum sodium value do not have a low osmolality. The clinical effects of hyponatremia are secondary to the associated low osmolality. Without a low osmolality, there is no movement of water into the intracellular space.

A patient with hyponatremia can have a low, normal, or high osmolality. A normal osmolality and hyponatremia occurs in pseudohyponatremia. Children with an elevated serum glucose concentration or another effective osmole (e.g., mannitol) have a high plasma osmolality and hyponatremia. The presence of a low osmolality indicates “true” hyponatremia. These patients are at risk for neurologic symptoms and require further evaluation to determine the etiology of their hyponatremia.

In some situations, true hyponatremia is present despite a normal or elevated plasma osmolality. The presence of an ineffective osmole, most commonly urea, increases the plasma osmolality, but, because it has the same concentration in the intracellular space, does not cause fluid to move into the extracellular space. There is no dilution of the serum sodium by water, and the sodium concentration remains unchanged if the ineffective osmole is eliminated. Most importantly, the ineffective osmole does not protect the brain from edema as a result of hyponatremia. Hence, a patient may develop symptoms from hyponatremia despite a normal or increased osmolality caused by uremia.

The role of determining the plasma osmolality in patients with hyponatremia is open to question. Pseudohyponatremia, a laboratory artifact, does not occur in most clinical laboratories and is simple to ascertain. Even if it is a possibility, hyperlipidemia is apparent by inspection of blood, which is lipemic. High serum protein almost never occurs in children; it is mostly an issue in adult disorders (e.g., multiple myeloma). Measuring a serum glucose level and evaluating for a history of intravenous mannitol easily assesses for hyponatremia secondary to increased effective osmoles. Finally, the presence of ineffective osmoles, such as urea or ethanol, confuses the usual assumption about true hyponatremia only occurring with a low plasma osmolality.

In patients with true hyponatremia, the next step in the diagnostic process is to clinically evaluate the patient's volume status. Patients with hyponatremia can be hypovolemic, hypervolemic, or euvolemic. The diagnosis of volume depletion relies on the usual findings with dehydration (see Chapter 47). Children with hypervolemia are edematous on physical examination. They may have ascites, pulmonary edema, pleural effusion, or hypertension.

Hypovolemic hyponatremia can have renal or nonrenal causes. When the losses are nonrenal and the kidney is working properly, there is renal retention of sodium, a normal homeostatic response to volume depletion. Thus, the urinary sodium concentration is low, typically less than 10?mEq/L, although sodium conservation in neonates is less avid. In contrast, when the kidney is the cause of the sodium loss, the urine will have a sodium concentration of greater than 20?mEq/L, reflecting the defect in renal sodium retention. Therefore, in the child with hypovolemic hyponatremia, the urine sodium is very useful in differentiating between renal and nonrenal causes. The interpretation of the urine sodium is challenging with diuretics because it is high when diuretics are being used but low after the diuretic effect is gone. This becomes an issue only when the diuretic use is surreptitious. The urine sodium is not useful if a metabolic alkalosis is present; the urine chloride must be used instead (see Chapter 45.8).

Differentiating among the nonrenal causes of hypovolemic hyponatremia is usually facilitated by the history. The renal causes are more challenging to distinguish. The serum potassium value is often helpful in this regard. Specifically, a high serum potassium concentration is associated with disorders in which the sodium wasting is due to absent or ineffective aldosterone.

In the patient with hypervolemic hyponatremia, the urine sodium concentration is a helpful parameter. It is usually <10?mEq/L, except in the patient with renal failure. An elevated urine sodium concentration is a useful indication that a child may have acute tubular necrosis superimposed on one of the other causes of hypervolemic hyponatremia.

Treatment.

The management of hyponatremia is based on the pathophysiology of the specific etiology. In general, diseases that have a similar pathogenesis are treated similarly. In addition, the management of all causes requires judicious monitoring and avoidance of an overly quick normalization of the serum sodium concentration. Yet, a patient with severe symptoms, no matter the etiology, should be given a bolus of hypertonic saline to produce a small, rapid increase in the serum sodium.

With all causes of hyponatremia, it is important to avoid “overly rapid” correction of the hyponatremia. This is because rapid correction of hyponatremia may cause *central pontine myelinolysis* (CPM). This syndrome produces neurologic symptoms, including confusion, agitation, flaccid or spastic quadriparesis, and death. There are usually characteristic pathologic and radiologic changes in the brain, especially in the pons.

CPM is more common in patients who are treated for chronic hyponatremia than for acute hyponatremia. Presumably this is based on the adaptation of brain cells to the hyponatremia. The reduced intracellular osmolality that is an adaptive mechanism for chronic hyponatremia makes brain cells susceptible to dehydration during rapid correction of the hyponatremia, and this may be the mechanism of CPM. Even though CPM is rare in pediatric patients, it is advisable to avoid correcting the serum sodium by more than 12?mEq/L each day. This guideline does not apply to acute hyponatremia, as may occur with water intoxication, because the hyponatremia is more often symptomatic and there has not been time for the adaptive decrease in brain osmolality. The consequences of brain edema in acute hyponatremia exceed the small risk of CPM.

Patients with hyponatremia can have severe neurologic symptoms such as seizures and coma. The seizures from hyponatremia are generally poorly responsive to anticonvulsants. The child with hyponatremia and severe symptoms needs to receive treatment that will quickly reduce cerebral edema. This is best accomplished by increasing the extracellular osmolality so that water moves down its osmolar gradient from the intracellular space to the extracellular space.

Intravenous hypertonic saline rapidly increases the serum sodium, and the effect on serum osmolality leads to a decrease in brain edema. Each milliliter of 3% sodium chloride increases the serum sodium by approximately 1?mEq/L. A child with active symptoms often improves after receiving 4–6?mL/kg of 3% sodium chloride.

The child with hypovolemic hyponatremia has a deficiency in sodium and may have a deficiency in water. The cornerstone of therapy is to replace the sodium deficit and any water deficit that is present. The first step in any dehydrated patient is to restore the intravascular volume with isotonic saline. This is frequently needed in hyponatremic dehydration because the low serum osmolality causes water to move intracellularly, further depleting the intravascular volume. Ultimately, complete restoration of intravascular volume suppresses ADH production, which permits excretion of the excess water. Chapter 47 discusses the management details of hyponatremic dehydration. Close monitoring of the sodium concentration is essential to avoid overly rapid correction, especially given the water diuresis that may occur with restoration of the intravascular volume.

The management of hypervolemic hyponatremia is difficult. These patients have an excess of both water and sodium. Administration of sodium leads to worsening volume overload and edema. In addition, these patients are retaining water and sodium because of their ineffective intravascular volume or renal insufficiency. The cornerstone of therapy is water and sodium restriction because these patients are overloaded. Diuretics may be helpful by causing excretion of both sodium and water. Patients with low albumin due to nephrotic syndrome have a better response to diuretics after an infusion of albumin. A child with congestive heart failure may have an increase in renal water and sodium excretion if there is an improvement in cardiac output. This will “turn off” the regulatory hormones that are causing renal water (ADH) and sodium (aldosterone) retention. The patient with renal failure cannot respond to any of these therapies except fluid restriction. Insensible fluid losses eventually result in an increase in the sodium concentration as long as insensible and urinary losses are greater than intake. A more definitive approach in children with renal failure is to perform dialysis, which removes water and sodium.

In isovolemic hyponatremia, there is usually an excess of water and a mild sodium deficit. Therapy is directed at eliminating the excess water. The child with excessive water intake loses water in the urine because ADH production is turned off as a result of the low plasma osmolality. It takes time to eliminate the excess water, and limiting water intake allows this process to occur more quickly. For acute, symptomatic hyponatremia due to water intoxication, hypertonic saline may be needed to reverse cerebral edema. For chronic hyponatremia from poor solute intake, the child needs to receive an appropriate formula, and excess water intake should be eliminated.

Hormone replacement is the cornerstone of therapy for the hyponatremia of hypothyroidism or cortisol deficiency. Correction of the underlying defect permits appropriate elimination of the excess water. SIADH is a condition of excess water with a limited ability of the kidney to excrete water. The mainstay of therapy is fluid restriction. The sodium concentration will increase as long as intake of water is less than insensible losses. Fluid restriction obviously requires time and, thus, there is a temptation to treat these patients with normal saline or hypertonic saline. However, therapy with saline can create problems in children with SIADH. Infusions of saline temporarily increase the sodium concentration, but increase the child's blood pressure and this causes the kidneys to eliminate almost all of the sodium,

eliminating any benefit from the therapy. In addition, the water contained in the saline is retained and thus the hyponatremia may actually worsen. Saline, by itself, is likely to produce hypertension and minimal long-term therapeutic benefit.

Furosemide is more successful in the patient with SIADH and severe hyponatremia. Even in a patient with SIADH, furosemide causes an increase in water and sodium excretion. The loss of sodium is somewhat counterproductive, but this sodium can be replaced with hypertonic saline. Because the patient has a net loss of water and the urinary losses of sodium have been replaced, there is an increase in the sodium concentration but no significant increase in blood pressure.

Treatment of chronic SIADH is challenging. Fluid restriction in children is difficult for nutritional and behavioral reasons. The mainstays of adult therapy, demeclocycline and lithium, which blunt the effect of ADH, are problematic in children because of their potential toxicity. Another option is chronic furosemide therapy with sodium supplementation.

45.4 Potassium

POTASSIUM METABOLISM

Body Content and Physiologic Function.

The intracellular concentration of potassium, approximately 150?mEq/L, is much higher

---

than the plasma concentration (see Fig. 45–3). The majority of body potassium is contained in muscle. As muscle mass increases, there is an increase in body potassium. There is thus an increase in body potassium during puberty, which is more significant in boys. The majority of extracellular potassium is in bone; less than 1% of total body potassium is in plasma.

Because most potassium is intracellular, the plasma concentration does not always reflect the total body potassium content. A variety of conditions alter the distribution of potassium between the intracellular and extracellular compartments. The Na^+ ,K^+ -ATPase maintains the high intracellular potassium concentration by pumping sodium out of the cell and potassium into the cell. This balances the normal leak of potassium out of cells via potassium channels, which is driven by the favorable chemical gradient. Insulin increases potassium movement into cells by activating the Na^+ ,K^+ -ATPase. Because hyperkalemia stimulates insulin secretion, this may have a protective effect during hyperkalemia. Acid-base status affects potassium distribution, probably via potassium channels and the Na^+ ,K^+ - ATPase. A decrease in pH drives potassium extracellularly; an increase in pH has the opposite effect. ß-Adrenergic agonists stimulate the Na^+ ,K^+ -ATPase, increasing the cellular uptake of potassium. This may also be protective in that hyperkalemia stimulates adrenal release of catecholamines. a-Adrenergic agonists and exercise cause a net movement of potassium out of the intracellular space. An increase in plasma osmolality, as with mannitol infusion, leads to water movement out of the cells and potassium follows as a result of solvent drag. The serum potassium concentration increases by approximately 0.6?mEq/L with each 10-mOsm increase in the plasma osmolality. This occurs in diabetic ketoacidosis as a result of the increase in osmolality from hyperglycemia. Hyperglycemia in patients without insulin deficiency does not increase the plasma potassium concentration because the secondary insulin production causes potassium to move intracellularly.

The high intracellular concentration of potassium, the principal intracellular cation, is maintained via the Na^+ ,K^+ -ATPase. The resulting chemical gradient is used to produce the resting membrane potential of cells. Potassium is necessary for the electrical responsiveness of nerve and muscle cells, and for the contractility of cardiac, skeletal, and smooth muscle. The changes in membrane polarization that occur during muscle contraction or nerve conduction make these cells susceptible to changes in serum potassium levels. The ratio of intracellular to extracellular potassium determines the threshold for a cell to generate an action potential and the rate of cellular repolarization. The intracellular potassium concentration affects cellular enzymes and the intracellular pH. Low intracellular potassium raises the pH while high intracellular potassium lowers the pH. These acid-base changes modify cell functions. Potassium is necessary for maintaining cell volume because of its important contribution to intracellular osmolality.

Intake.

Potassium is plentiful in food. Dietary consumption varies considerably, even though 1–2?mEq/kg is the recommended intake. The intestines normally absorb approximately 90% of ingested potassium. Most absorption occurs in the small intestine, whereas the colon exchanges body potassium for luminal sodium. Regulation of intestinal losses normally has a minimal role in maintaining potassium homeostasis, although renal failure, aldosterone, and glucocorticoids increase colonic secretion of potassium. The increase in intestinal losses in the setting of renal failure and hyperkalemia, which stimulates aldosterone production, is clinically significant, helping to protect against hyperkalemia. Colonic secretion is important following an acute potassium load. Patients with kidney failure who develop constipation or receive an ACE-inhibitor, an indirect inhibitor of aldosterone production, may have less colonic secretion, and therefore develop hyperkalemia. However, colonic secretion is never more than a small part of overall potassium excretion.

Excretion.

There is some loss of potassium in sweat, but this is normally minimal. The colon has the ability to eliminate some potassium. In addition, following an acute potassium load, much of the potassium, more than 40%, moves intracellularly, through the actions of epinephrine and insulin, which are produced in response to hyperkalemia. This provides transient protection from hyperkalemia, but most ingested potassium is eventually excreted in the urine. The kidneys are the principal regulator of chronic potassium balance and they alter excretion in response to a variety of signals. Potassium is freely filtered at the glomerulus, but 90% is reabsorbed before the distal tubule and collecting duct, the principal sites of potassium regulation. The distal tubule and the collecting duct have the ability to absorb and secrete potassium. It is the amount of tubular secretion that regulates the amount of potassium that appears in the urine. The plasma potassium concentration directly influences secretion in the distal nephron. As the potassium concentration increases, secretion increases.

The principal hormone regulating potassium secretion is aldosterone, which is released by the adrenal cortex in response to increased plasma potassium. Its main site of action is the cortical collecting duct, where aldosterone stimulates sodium movement from the tubule into the cells. This creates a negative charge in the tubular lumen, facilitating potassium excretion. In addition, the increased intracellular sodium stimulates the basolateral Na^+ ,K^+ -ATPase, causing more potassium to move into the cells lining the cortical collecting duct. Urinary potassium excretion is also increased by glucocorticoids, ADH, high urinary flow rate, and high sodium delivery to the distal nephron. In contrast, potassium excretion is decreased by insulin, catecholamines, and urinary ammonia. Loop and thiazide diuretics increase potassium secretion by increasing sodium delivery to the distal nephron and increasing the urinary flow rate in the distal nephron. Whereas ADH increases potassium secretion, it also causes water reabsorption, decreasing urinary flow. The net effect is that ADH has little overall impact on potassium balance. Alkalosis causes potassium to move into cells, including the cells lining the collecting duct. This increases potassium secretion, and because acidosis has the opposite effect, it decreases potassium secretion.

The kidney can dramatically vary potassium excretion in response to changes in intake. Normally, about 10–15% of the filtered load is excreted. In an adult, excretion of potassium can vary between 5 and 1,000?mEq per day.

HYPERKALEMIA

Hyperkalemia—because of the potential for lethal arrhythmias—is one of the most alarming electrolyte abnormalities.

Etiology and Pathophysiology.

There are three basic mechanisms that cause hyperkalemia (Box 45–4). In the individual patient, the etiology is sometimes multifactorial.

Fictitious hyperkalemia is very common in children because of the difficulties in obtaining blood specimens. This is usually due to hemolysis during phlebotomy, but it can be the result of prolonged tourniquet application or fist clinching, which cause local potassium release from muscle.

The serum potassium level is normally 0.4?mEq/L higher than the plasma value, secondary to release from cells during clot formation. This phenomenon is exaggerated with thrombocytosis because of potassium release from platelets. For every 100,000/m^3 increase in the platelet count, the serum potassium increases by approximately 0.15?mEq/L. This also occurs with the marked white blood cell elevations sometimes seen with leukemia. Elevated white blood cells counts, typically greater than 200,000/m^3 , can cause a dramatic elevation in the serum potassium concentration. Analysis of a plasma sample usually provides an accurate result. It is important to analyze the sample promptly to avoid potassium release from cells. This occurs if the sample is stored in the cold, whereas room temperature

storage can lead to cellular uptake of potassium and spurious hypokalemia.

Because of the kidney's ability to excrete potassium, it is unusual for excessive intake, by itself, to cause hyperkalemia. This can occur in a patient who is receiving large quantities of intravenous or oral potassium as a result of excessive losses that are no longer present. Frequent or rapid blood transfusions can acutely increase the potassium level because of the potassium content of blood, which is variably elevated. Increased intake may precipitate hyperkalemia if there is an underlying defect in potassium excretion.

The intracellular space has a very high potassium concentration, so a shift of potassium from the intracellular space to the extracellular space can have a significant impact on the plasma potassium. This occurs with metabolic acidosis, but the effect is minimal with an organic acid (e.g., lactic acidosis or ketoacidosis). A respiratory acidosis has less impact than a metabolic acidosis. Cell destruction, as seen with rhabdomyolysis, tumor lysis syndrome, tissue necrosis, or hemolysis, releases potassium into the extracellular milieu. The potassium from red blood cells in internal bleeding, such as hematomas, is resorbed and enters the extracellular space.

Normal doses of succinylcholine or ß-blockers and fluoride or digitalis intoxication all cause a shift of potassium out of the intracellular compartment. Succinylcholine should not be used during anesthesia in patients at risk for hyperkalemia. ß-blockers prevent the normal cellular uptake of potassium mediated by binding of ß-agonists to the $ß_2$ -adrenergic receptors. Potassium release from muscle cells occurs during exercise, and levels can increase by 1–2?mEq/L with high activity. With an increased plasma osmolality, water moves from the intracellular space and potassium follows as a result of solvent drag. This occurs with hyperglycemia, although in nondiabetic patients the resultant increase in insulin causes potassium to move intracellularly. In diabetic ketoacidosis, the absence of insulin causes potassium to leave the intracellular space, and this is compounded by the hyperosmolality. The effect of hyperosmolality causes a transcellular shift of potassium into the extracellular space after mannitol or hypertonic saline infusions. Malignant hyperthermia, which is triggered by some inhaled anesthetics, causes muscle release of potassium. Hyperkalemic periodic paralysis is an autosomal dominant disorder caused by a mutated sodium channel and results in episodic cellular release of potassium and attacks of paralysis.

The kidneys excrete most of the daily potassium intake so a decrease in kidney function can cause hyperkalemia. The decrease in potassium excretion and the risk of hyperkalemia is proportional to the degree of renal insufficiency. Newborn infants in general, and especially premature infants, have decreased kidney function at birth and thus are at increased risk for hyperkalemia, despite an absence of intrinsic renal disease.

A wide range of primary adrenal disorders, both hereditary and acquired, can cause decreased production of aldosterone, with secondary hyperkalemia (see Chapters 569 and 570). These patients typically have metabolic acidosis and salt wasting with hyponatremia. Children with more subtle adrenal insufficiency may only develop electrolyte problems during acute illnesses. With less severe adrenal insufficiency, hyponatremia may be the only electrolyte abnormality. Causes of acquired adrenal dysfunction include hemorrhage (e.g., Waterhouse-Friderichsen syndrome in meningococcemia), tuberculous, and autoimmune disease. The most common form of congenital adrenal hyperplasia, 21-hydroxylase deficiency, typically presents in infant boys with hyperkalemia, metabolic acidosis, hyponatremia, and volume depletion. Girls with this disorder usually are diagnosed as newborns because of their ambiguous genitalia; treatment prevents the development of electrolyte problems.

Renin, via angiotensin II, stimulates aldosterone production. A deficiency in renin, a result of kidney damage, can lead to decreased aldosterone production. Hyporeninemia occurs in many kidney diseases, with some of the more common pediatric causes listed in Box 45–4 . These patients typically have hyperkalemia and a metabolic acidosis, without hyponatremia. Some of these patients have impaired renal function, partially accounting for the hyperkalemia, but the impairment in potassium excretion is more extreme than expected for the degree of renal insufficiency.

A variety of renal tubular disorders impair renal excretion of potassium. Children with pseudohypoaldosteronism type 1 have hyperkalemia, metabolic acidosis, and salt wasting leading to hyponatremia and volume depletion; aldosterone levels are elevated. In the autosomal recessive variant, there is a defect in the renal sodium channel that is normally activated by aldosterone. These patients have severe symptoms, beginning in infancy. In the autosomal dominant form, patients have a defect in the aldosterone receptor, and the disease is milder, often

remitting in adulthood. Pseudohypoaldosteronism, type 2, also called *Gordon syndrome*, is an autosomal dominant disorder characterized by hypertension due to salt retention and impaired excretion of potassium and acid, leading to hyperkalemia and metabolic acidosis. Activating mutations in either WNK1 or WNK4, both serine-threonine kinases located in the distal nephron, cause Gordon syndrome.

Acquired renal tubular dysfunction, with an impaired ability to excrete potassium, occurs in a number of conditions. These disorders, all characterized by tubulointerstitial disease, are often associated with impaired acid secretion and a secondary metabolic acidosis. In some children, the metabolic acidosis is the dominant feature, although a high potassium intake may unmask the defect in potassium handling. The tubular dysfunction can cause renal salt wasting, potentially leading to hyponatremia. A defect in water handling, secondary nephrogenic diabetes insipidus, takes place in some children. This predisposes to dehydration and may lead to hypernatremia. Among the disorders listed in Box 45–4 , the children with obstructive uropathy, primarily posterior urethral valves, are at risk for the most significant tubular dysfunction. Because of the tubulointerstitial damage, these conditions may also cause hyperkalemia as a result of hyporeninemic hypoaldosteronism.

The risk of hyperkalemia resulting from medications is greatest in patients with underlying renal insufficiency. The predominant mechanism of medication-induced hyperkalemia is impaired renal excretion, even though ACE inhibitors may worsen hyperkalemia in anuric patients, probably by inhibiting gastrointestinal potassium loss, which is normally upregulated in renal insufficiency. The hyperkalemia caused by trimethoprim generally only occurs at the very high doses used to treat *Pneumocystis carinii* pneumonia in patients with AIDS. Potassium-sparing diuretics may easily cause hyperkalemia, especially because they are often used in patients who are receiving oral potassium supplements.

Clinical Manifestations.

The most import effects of hyperkalemia are due to the role of potassium in membrane polarization. The cardiac conduction system is usually the dominant concern. Electrocardiographic (ECG) changes begin with peaking of the T waves. This is followed, as the potassium level increases, by an increased PR interval, flattening of the P wave, and widening of the QRS complex. This can eventually progress to ventricular fibrillation. Asystole may also occur. Some patients have paresthesias, weakness, and tingling, but cardiac toxicity usually precedes these clinical symptoms, emphasizing the danger of assuming that an absence of symptoms implies an absence of danger.

Diagnosis.

The etiology of hyperkalemia is often readily apparent. Spurious hyperkalemia is very common in children, so a repeat potassium level is often appropriate. If there is a significant elevation of the white blood cells or platelets, then the repeat sample should be from plasma that is evaluated promptly. The history should initially focus on potassium intake, risk factors for transcellular shifts of potassium, medications that cause hyperkalemia, and the presence of signs of renal insufficiency such as oliguria or an abnormal urinalysis. Initial laboratory evaluation should include creatinine, BUN, and assessment of acid-base status. Many etiologies of hyperkalemia cause a metabolic acidosis, and a metabolic acidosis worsens hyperkalemia by the transcellular shift of potassium out of cells. Renal insufficiency is a common cause of the combination of metabolic acidosis and hyperkalemia. This association is also seen in diseases with aldosterone insufficiency or aldosterone resistance. Children with absent or ineffective aldosterone often have hyponatremia and volume depletion due to salt wasting. Genetic diseases such as congenital adrenal hyperplasia and pseudohypoaldosteronism usually present in infancy and should be strongly considered in the infant with hyperkalemia and metabolic acidosis, especially if hyponatremia is present. It is important to consider the various etiologies of a transcellular shift of potassium. In some of these disorders, the potassium continues to increase despite the elimination of all potassium intake, especially when there is concurrent renal insufficiency. This is potentially seen in tumor lysis syndrome, hemolysis, rhabdomyolysis, and other causes of cell death. All of these entities can cause concomitant hyperphosphatemia and hyperuricemia. Rhabdomyolysis produces an elevated creatinine phosphokinase (CPK) and hypocalcemia, whereas children with hemolysis have hemoglobinuria and a decreasing hematocrit. For the child with diabetes, an elevated blood glucose level suggests a transcellular shift of potassium.

When there is no clear etiology of hyperkalemia, the diagnostic approach should focus on differentiating decreased potassium excretion from the other etiologies. Measuring urinary potassium assesses renal excretion of potassium. The transtubular potassium gradient (TTKG) is a useful method to evaluate the renal response to hyperkalemia:

where $[K]_{urine}$ is the urine potassium concentration and $[K]_{plasma}$ is the plasma potassium concentration. The urine osmolality must be greater than the serum osmolality for the result to be valid. The TTKG normally varies widely, ranging from 5–15. The TTKG should be greater than 10 in the setting of hyperkalemia, assuming normal renal excretion of potassium. A TTKG of less than 8 during hyperkalemia suggests a defect in renal potassium excretion, which is usually due to lack of aldosterone or an inability to respond to aldosterone. Measurement of aldosterone is useful for differentiating these possible mechanisms. Patients with a lack of aldosterone respond to fludrocortisone, an oral mineralocorticoid, by increasing urinary potassium and decreasing the serum potassium. An appropriate TTKG with normal kidney function argues for a nonrenal cause of hyperkalemia.

Treatment.

The plasma potassium level, the ECG, and the risk of the problem worsening determine the aggressiveness of the therapeutic approach. High serum potassium levels and the presence of ECG changes require more vigorous treatment. An additional source of concern is the patient with increasing plasma potassium despite minimal intake. This can happen if there is cellular release of potassium (e.g., tumor lysis syndrome), especially in the setting of diminished excretion (e.g., renal failure).

The first action in a child with a concerning elevation of plasma potassium is to stop all sources of additional potassium (oral and intravenous). Washed red blood cells

can be used for patients who require blood transfusions. If the potassium level is greater than 6.0–6.5?mEq/L, an ECG should be obtained to help assess the urgency of the situation. The therapy of the hyperkalemia has two basic goals: (1) to stabilize the heart to prevent life-threatening arrhythmias and (2) to remove potassium from the body. The treatments that acutely prevent arrhythmias all have the advantage of working quickly (i.e., within minutes), but do not remove potassium from the body. Calcium stabilizes the cell membrane of heart cells, preventing arrhythmias. It is given over a few minutes intravenously and its action is almost immediate. Calcium should be given over 30 minutes in a patient receiving digitalis because it may cause arrhythmias. Bicarbonate causes potassium to move intracellularly, lowering the plasma potassium. It is especially efficacious in a patient with a metabolic acidosis. Insulin causes potassium to move intracellularly, but it must be given with glucose to avoid hypoglycemia. The combination of insulin and glucose works within 30 minutes. Nebulized albuterol, by stimulation of ß$_1$ -receptors, leads to intracellular movement of potassium. This has the

advantage of not requiring an intravenous route of administration, allowing it to be given concurrently with the other measures.

It is important to begin measures that remove potassium from the body. Because none of these work quickly, it is important to start them as soon as possible. In patients who are not anuric, a loop diuretic increases renal excretion of potassium. This may require a high dose in a patient with significant renal insufficiency. Sodium polystyrene sulfonate (Kayexalate) is an exchange resin that is given either rectally or orally. Sodium in the resin is exchanged for body potassium and the potassium-containing resin is then excreted from the body. Some patients require dialysis for acute potassium removal. Dialysis is often necessary if there is severe renal failure or if there is an especially high rate of endogenous potassium release as is sometimes present with tumor lysis syndrome or rhabdomyolysis. Hemodialysis rapidly lowers plasma potassium levels. Peritoneal dialysis is not nearly as quick or reliable, even though it is usually adequate as long as the acute problem can be managed with medications and the endogenous release of potassium is not extremely high.

Chronic management of hyperkalemia includes reducing intake via dietary changes and eliminating or reducing medications that cause hyperkalemia. Some patients require medications to increase potassium excretion. These include sodium polystyrene sulfonate and loop or thiazide diuretics. Some infants with chronic renal failure may need to start dialysis to allow adequate caloric intake without hyperkalemia. It is unusual for an older child to require dialysis principally to control chronic hyperkalemia. The disorders that are due to a deficiency in aldosterone respond to replacement therapy with fludrocortisone.

HYPOKALEMIA

Hypokalemia is common in children, with most cases related to gastroenteritis.

Etiology and Pathophysiology.

There are four basic mechanisms of hypokalemia (Box 45–5). Low intake, nonrenal losses, and renal losses are all associated with total body potassium depletion. With a transcellular shift, there is no change in total body potassium, although there may be concomitant potassium depletion resulting from other factors. Spurious hypokalemia occurs in patients with leukemia and very elevated white blood cell counts if plasma for analysis is left at room temperature, permitting the white cells to take up potassium from the plasma. High white counts may cause fictitious hyperkalemia if a serum sample is analyzed or a plasma sample is stored in the cold.

Because the intracellular potassium concentration is much higher than the plasma level, a significant amount of potassium can move into cells without markedly changing the intracellular potassium concentration. Alkalemia is one of the more common causes of a transcellular shift. The effect is much greater with a metabolic alkalosis than with a respiratory alkalosis. The impact of exogenous insulin on potassium movement into cells is substantial in patients with diabetic ketoacidosis. It can be endogenous insulin when a patient is given a bolus of glucose. Both endogenous (e.g., epinephrine in stress) and exogenous (e.g., albuterol) s-adrenergic agonists stimulate cellular uptake of potassium. Theophylline overdose, barium intoxication, and toluene intoxication from paint or glue sniffing cause a transcellular shift hypokalemia, often with severe clinical manifestations. Children with hypokalemic periodic paralysis, a rare autosomal dominant disorder, have acute cellular uptake of potassium, producing the symptomatology (see Chapter 602).

Inadequate potassium intake occurs in anorexia nervosa; accompanying bulimia and laxative or diuretic abuse exacerbates the potassium deficiency. Sweat losses of potassium can be significant during vigorous exercise in a hot climate. Associated volume

Box 45.4-5. Causes of Hypokalemia

SPURIOUS

- High white blood cell count

TRANSCELLULAR SHIFTS

- Alkalemia
- Insulin
- ß-adrenergic agonists
- Drugs/toxins (theophylline, barium, toluene)
- Hypokalemic periodic paralysis (MIM[*] 170400)

DECREASED INTAKE

EXTRARENAL LOSSES

- Diarrhea
- Laxative abuse
- Sweating

RENAL LOSSES

- With metabolic acidosis

Liddle syndrome (MIM 177200)

*MIM refers to the database number from the Mendelian Inheritance in Man (http://www3.ncbi.nlm.nih.gov/Omim/).
†Most cases of proximal RTA are not due to this primary genetic disorder. Proximal RTA is usually part of Fanconi syndrome, which has multiple etiologies (see Chapter 521).

depletion and hyperaldosteronism increases renal losses of potassium (see later text). Diarrhea has a high concentration of potassium and the resulting hypokalemia is usually associated with a metabolic acidosis resulting from stool losses of bicarbonate. In contrast, a normal acid-base balance or a mild metabolic alkalosis is seen with laxative abuse.

Urinary potassium wasting may be accompanied by a metabolic acidosis (proximal or distal renal tubular acidosis [RTA]). In diabetic ketoacidosis, although often associated with normal plasma potassium caused by transcellular shifts, there is significant total body potassium depletion from urinary losses due to the osmotic diuresis, and the potassium level may dramatically decrease with insulin therapy (see Chapter 583). Both the polyuric phase of acute tubular necrosis and postobstructive diuresis cause transient, highly variable potassium wasting and

may be associated with a metabolic acidosis. Tubular damage, either directly from medications or secondary to interstitial nephritis, is often accompanied by other tubular losses, including magnesium, sodium, and water. Such tubular damage may cause a secondary RTA with a metabolic acidosis. Isolated magnesium deficiency causes renal potassium wasting. Penicillin is an anion that is excreted in the urine, resulting in increased potassium excretion because the penicillin anion must be accompanied by a cation. Hypokalemia from penicillin only occurs with the sodium salt of penicillin, not with the potassium salt.

Urinary potassium wasting is often accompanied by a metabolic alkalosis. This is usually associated with increased aldosterone, which increases urinary potassium and acid losses, contributing to the hypokalemia and the metabolic alkalosis. Other mechanisms often contribute to both the potassium losses and the metabolic alkalosis. With emesis or nasogastric suction there is gastric loss of potassium, but this is fairly minimal given the low potassium content of gastric fluid (~10?mEq/L). More important is the gastric loss of HCl, leading to a metabolic alkalosis and a state of volume depletion. The kidney compensates for the metabolic alkalosis by excreting bicarbonate in the urine, but there is obligate loss of potassium and sodium with the bicarbonate. The volume depletion increases aldosterone levels, which prevents correction of the metabolic alkalosis and hypokalemia until the volume depletion is corrected. Urinary chloride is low as a response to the volume depletion. Because the volume depletion is secondary to chloride loss, this is a state of chloride deficiency. There were cases of chloride deficiency resulting from infant formula deficient in chloride, which caused a metabolic alkalosis with hypokalemia and low urine chloride. Current infant formula is not deficient in chloride. A similar mechanism occurs in cystic fibrosis because of a chloride loss in sweat. In congenital chloride-losing diarrhea, an autosomal recessive disorder, there is high stool loss of chloride, leading to metabolic alkalosis, an unusual sequelae of diarrhea. Because of stool potassium losses, chloride deficiency, and metabolic alkalosis, these patients have hypokalemia. During respiratory acidosis, there is renal compensation, with retention of bicarbonate and excretion of chloride. After the respiratory acidosis is corrected, patients have chloride deficiency and post-hypercapnic alkalosis with secondary hypokalemia. Patients with chloride deficiency, metabolic alkalosis, and hypokalemia have urinary chloride of less than 10?mEq/L. Loop and thiazide diuretics lead to hypokalemia, metabolic alkalosis, and chloride deficiency. During treatment, these patients have high urine chloride resulting from the effect of the diuretic. However, after the diuretics are discontinued, there is residual chloride deficiency, the urinary chloride is appropriately low, and neither the hypokalemia nor the alkalosis resolves until the chloride deficiency is corrected.

The combination of metabolic alkalosis, hypokalemia, high urine chloride, and normal blood pressure is characteristic of Bartter syndrome, Gitelman syndrome, and current diuretic use. These patients have high urinary losses of potassium and chloride despite a state of relative volume depletion with secondary hyperaldosteronism. Bartter and Gitelman syndromes are autosomal recessive disorders caused by defects in tubular transporters (see Chapter 523). Bartter syndrome is usually associated with hypercalciuria, often with nephrocalcinosis, whereas children with Gitelman syndrome have low urinary calcium losses, but hypomagnesemia due to urinary magnesium losses.

In the presence of high aldosterone, there is urinary loss of potassium, hypokalemia, metabolic alkalosis, and an elevated urinary chloride. There is also renal retention of sodium, leading to hypertension. Primary hyperaldosteronism from adenoma or hyperplasia is much less common in children than in adults (see Chapter 572).

Glucocorticoid-remedial aldosteronism, an autosomal dominant disorder that leads to high levels of aldosterone, is often diagnosed in childhood.

Increased aldosterone may be secondary to increased renin production. Renal artery stenosis leads to hypertension from increased renin and secondary hyperaldosteronism. The increased aldosterone can cause hypokalemia and metabolic alkalosis, even though most patients have normal electrolytes. Renin-producing tumors, which are extremely rare, can cause hypokalemia.

There are a variety of disorders that cause hypertension and hypokalemia without increased aldosterone. Some are due to increased levels of mineralocorticoids other than aldosterone. This occurs in two forms of congenital adrenal hyperplasia (see Chapter 570). In 11s-hydroxylase deficiency, which is associated with virilization, 11-deoxycorticosterone is elevated, which causes variable hypertension and hypokalemia. A similar mechanism, increased DOC, occurs in 17a hydroxylase deficiency, but these patients are more uniformly hypertensive and hypokalemic, and have a defect in sex hormone production. Cushing syndrome, frequently associated with hypertension, less commonly causes metabolic alkalosis and hypokalemia. This is secondary to the mineralocorticoid activity of cortisol. In 11s-hydroxysteroid dehydrogenase deficiency, an autosomal recessive disorder, the enzymatic defect prevents conversion of cortisol to cortisone in the kidney. Because cortisol binds and activates the aldosterone receptor, these children have all the features of excessive mineralocorticoids, including hypertension, hypokalemia, and metabolic alkalosis. Patients with this disorder, which is also called “apparent mineralocorticoid excess,” respond to spironolactone therapy, which blocks the mineralocorticoid receptor. An acquired form of 11s-hydroxysteroid dehydrogenase deficiency occurs from the ingestion of substances that inhibit this enzyme. A classic example is glycyrrhizic acid, which is found in natural licorice. Liddle syndrome is an autosomal dominant disorder that results from an activating mutation of the distal nephron sodium channel that is normally upregulated by aldosterone. Patients have the characteristics of hyperaldosteronism—hypertension, hypokalemia, and alkalosis—but low serum aldosterone levels. These patients respond to the potassium-sparing diuretics (triamterene and amiloride) that inhibit this sodium channel.

Clinical Manifestations.

The heart and skeletal muscle are especially vulnerable to hypokalemia. ECG changes include a flattened T wave, depressed ST segment, and appearance of a U wave, which is located between the T wave, if still visible, and P wave. Ventricular fibrillation and torsades de pointes may occur, although usually only in the context of underlying heart disease. Hypokalemia makes the heart especially susceptible to digitalis-induced arrhythmias such as supraventricular tachycardia, ventricular tachycardia, and heart block (also see Chapter 428).

The clinical consequences in skeletal muscle include muscle weakness and cramps. Paralysis is a possible complication, generally only at levels less than 2.5?mEq/L. This usually starts with the legs, followed by the arms. Respiratory paralysis may require mechanical ventilation. Some patients develop rhabdomyolysis; the risk increases with exercise. Hypokalemia slows gastrointestinal motility. This manifests as constipation or, with levels less than 2.5?mEq/L, ileus may occur. Hypokalemia impairs bladder function, potentially leading to urinary retention.

Hypokalemia causes polyuria and polydipsia by two mechanisms: primary polydipsia and impaired urinary concentrating ability, producing a nephrogenic diabetes insipidus. Hypokalemia stimulates renal ammonia production, which is clinically significant if hepatic failure is present because the liver cannot metabolize the ammonia. Hypokalemia may therefore worsen hepatic encephalopathy.

Chronic hypokalemia may cause kidney damage, including interstitial nephritis and renal cysts. In children, chronic hypokalemia, as in Bartter syndrome, leads to poor linear growth.

Diagnosis.

Most causes of hypokalemia are readily apparent from the history. It is important to review the child's diet, gastrointestinal losses, and medications. Both emesis and diuretic use can be surreptitious. The presence of hypertension suggests excess mineralocorticoids. Concomitant electrolyte abnormalities are useful clues. The combination of hypokalemia and metabolic acidosis is characteristic of diarrhea and of distal and proximal RTA. A concurrent metabolic alkalosis is characteristic of emesis or nasogastric losses, aldosterone excess, use of diuretics, and Bartter and Gitelman syndromes. Alkalosis is also associated with a transcellular shift of potassium intracellularly and increased urinary losses of potassium.

If a clear etiology is not apparent, the measurement of urinary potassium distinguishes between renal and extrarenal losses. The kidneys should conserve potassium in the presence of extrarenal losses. Urinary potassium losses can be assessed with a 24-hour urine collection, a spot potassium/creatine ratio, a fractional excretion of potassium, or calculation of the TTKG, which is the most widely used approach in children:

where $[K]_{urine}$ is the urine potassium concentration and $[K]_{plasma}$ is the plasma potassium concentration.

The urine osmolality must be greater than the serum osmolality for the result to be valid. A TTKG of more than 4 in the presence of hypokalemia suggests excessive urinary losses of potassium. The urinary potassium excretion can be misleading if the stimulus for renal losses, such as a diuretic, is no longer present.

Treatment.

Factors that influence the therapy of hypokalemia include the potassium level, clinical symptoms, renal function, presence of transcellular shifts of potassium, ongoing losses, and the patient's ability to tolerate oral potassium. Severe, symptomatic hypokalemia receives more aggressive treatment. Supplementation is more cautious if renal function is decreased because of the kidney's limited ability to excrete excessive potassium. The plasma potassium level does not always provide

an accurate estimation of the total body potassium deficit. This is because there may be shifts of potassium from the intracellular space to the plasma. Clinically, this occurs most commonly with metabolic acidosis and the insulin deficiency of diabetic ketoacidosis; the plasma potassium underestimates the degree of total body potassium depletion. As these problems are corrected, potassium moves into the intracellular space so these patients require more potassium supplementation to correct their hypokalemia. Likewise, the presence of a transcellular shift of potassium into cells indicates that the total body potassium depletion is less severe. Patients who have ongoing losses of potassium need correction of their deficit and replacement of the ongoing losses.

Because of the risk of hyperkalemia, intravenous potassium should be used cautiously. Oral potassium is safer, albeit not as rapid in urgent situations. The dose of intravenous potassium is 0.5–1?mEq/kg, usually given over 1?hr. The adult maximum dose is 40?mEq. Conservative dosing is generally preferred. Potassium chloride is the usual choice for supplementation, although the presence of concurrent electrolyte abnormalities may dictate other options. Patients with acidosis and hypokalemia can receive potassium acetate or potassium citrate. If hypophosphatemia is present, then some of the potassium deficit can be replaced with potassium phosphate. It is sometimes possible to decrease ongoing losses of potassium. For patients with excessive urinary losses, potassium-sparing diuretics are effective, but they need to be used cautiously in patients with renal insufficiency. If hypokalemia, metabolic alkalosis, and volume depletions are present (e.g., with gastric losses), then restoration of intravascular volume with adequate chloride will decrease urinary potassium losses. Disease-specific therapy is effective in many of the genetic tubular disorders.

45. Calcium

CALCIUM METABOLISM

Body Content and Physiologic Function.

Ninety-nine percent of body calcium is in bone, mostly as hydroxyapatite. During growth, bone mass increases faster than body weight, which necessitates a concomitant increase in body calcium. In infants, there is approximately 400?mg/kg of calcium, whereas adults have 950?mg/kg of calcium. Calcium has a number of crucial physiologic functions, including blood coagulation, cellular communication, exocytosis, endocytosis, muscle contraction, and neuromuscular transmission. There are two principal goals of calcium homeostasis. First, there must be adequate net intake of calcium to permit normal skeletal growth and mineralization. Second, there is tight regulation of the serum calcium concentration in order to permit normal physiologic functioning. The second goal takes precedence over the first goal: skeletal mineralization may be sacrificed to maintain a normal serum calcium level.

Measurement of Serum Calcium.

Because calcium is a divalent cation, the units mmol/L and mEq/L are not equivalent, and there are three different units used for its measurement (Table 45–1). Most laboratories in the United States use mg/dL when reporting the total calcium concentration. However, the ionized calcium concentration is more physiologically relevant than the total calcium concentration, and its value may be reported in any of the three possible units. It is critical to know whether a calcium value is total or ionized and to know which units are used.

Slightly less than half of the total serum calcium exists in the free or ionized form. Most of the remainder is bound to protein (mostly albumin), whereas a smaller percentage, about 10%, complexes with anions such as phosphate, citrate, or sulfate. The ionized calcium is relevant for cell function, and the body's homeostatic system regulates the ionized calcium concentration. Nevertheless, it is the total calcium that is usually measured.

In general, the total calcium provides a satisfactory assessment of physiologic calcium. However, there are a few clinical situations in which the total calcium is not an adequate surrogate for the ionized calcium concentration. The most common and severe problem is the presence of hypoalbuminemia, such as patients with nephrotic syndrome, liver disease, capillary

TABLE 45.-1 -- Conversion Factors for Calcium, Magnesium, and Phosphorus			
	Unit	**Conversion Factor**	**Unit**
Calcium	mg/dL	0.25	mmol/L
	mEq/L	0.5	mmol/L
	mg/dL	0.5	mEq/L
Magnesium	mg/dL	0.411	mmol/L
	mEq/L	0.5	mmol/L
	mg/dL	0.822	mEq/L
Phosphorus	mg/dL	0.32	mmol/L

Note: Values in the left unit column are converted into the right unit column via multiplying by the conversion factor (e.g., calcium of 10?mg/dL times 0.25 equals 2.5?mmol/L). Division of the right unit column by the conversion factor converts to the units of the left unit column.

leak, or protein-losing enteropathy. Each 1?g/dL of albumin in the serum binds about 0.8?mg/dL of calcium. A low total calcium concentration may be normal in a patient with significant hypoalbuminemia. The following formula can be used to “correct” the total calcium concentration in the setting of hypoalbuminemia:

where Ca_c is total calcium corrected and Ca_m is total calcium measured.

When using this formula, a total calcium concentration that is in the normal range after correction suggests that the patient has a normal ionized calcium concentration; a high or low value indicates hypercalcemia or hypocalcemia, respectively. Unfortunately, this formula is not universally accurate and an ionized calcium concentration should be obtained when the albumin is low and there is clinical suspicion of an abnormal ionized calcium concentration. This is especially true in sicker patients, because very ill children are more likely to have an abnormal calcium concentration, and they frequently have other disturbances that make the total calcium concentration a less accurate gauge of the ionized calcium concentration.

Some of the limitations of the above formula are due to other factors affecting the relationship between the total calcium and the ionized calcium. Serum globulin binds a small amount of calcium and, therefore, has a small impact on this relationship. The serum pH influences the percentage of calcium that is bound to albumin and other ions such as phosphate. Alkalemia produces more binding of calcium and acidemia causes less binding of calcium. As the pH decreases, less calcium is bound, and the ionized calcium concentration increases. This can be clinically relevant when bicarbonate is administered to correct acidosis; the increasing pH increases the amount of bound calcium and the ionized calcium decreases, possibly producing symptoms.

Regulation of Calcium.

A complex hormonal system regulates the serum calcium concentration. Acutely, this system relies on the large reservoir of calcium that is present in bone. Chronically, there must be a balance between calcium intake from the gastrointestinal tract and calcium losses, mostly via the urine. In growing children, a net positive calcium balance is necessary for growth and skeletal mineralization.

Maintenance and accretion of body calcium require gastrointestinal absorption, which occurs predominantly in the duodenum and jejunum. Breast milk (300?mg/L), formula (~530?mg/L), and cow's milk (~1,200?mg/L) are excellent sources of calcium, and children in the United States receive most of their dietary calcium from milk and other dairy products. The recommended intake of calcium varies with age (see Chapter 40). Even though there is some passive calcium absorption when dietary intake is high, an active transport system is responsible for most gastrointestinal absorption, especially when dietary intake is low. Through the production of calcium-binding proteins and activation of a calcium pump on the gastrointestinal epithelial cells, 1,25-dihydroxyvitamin D stimulates the active transport of calcium. Without adequate 1,25-dihydroxyvitamin D, the active form of vitamin D, gastrointestinal absorption of calcium decreases substantially.

The synthesis of vitamin D in the skin occurs when its precursor, 7-dehydrocholesterol, is exposed to ultraviolet light, typically from the sun. The main dietary sources of vitamin D are fortified foods, principally milk or formula, and vitamin supplements. The production of 1,25-dihydroxyvitamin D requires that vitamin D is first hydroxylated in the liver, producing 25-hydroxyvitamin D. In the kidney, the enzyme 1a-hydroxylase converts 25-dihyroxyvitamin D into 1,25-dihydroxyvitamin D.

Modifying synthesis of 1,25-dihydroxyvitamin D is an important mechanism for regulating calcium balance. Parathyroid hormone (PTH), released by the parathyroid gland in response to low serum calcium levels, stimulates the 1a-hydroxylase in the kidney to produce more 1,25-dihydroxyvitamin D, ultimately leading to increased absorption of calcium. A calcium-sensing receptor in the parathyroid gland dictates the release of PTH.

Whereas the actions of 1,25-dihydroxyvitamin D on the intestinal tract control calcium intake, the kidneys control calcium excretion. The calcium in the plasma that is not bound to protein, including the ionized calcium and calcium complexed to anions, is freely filtered by the glomerulus and enters the proximal tubule. About 99% of the filtered calcium is reabsorbed by the tubules, with 50% or more reclaimed in the proximal tubule. The loop of Henle, the distal tubule, and the collecting duct are other sites of calcium reabsorption. In the proximal tubule and the loop of Henle, calcium reabsorption parallels sodium reabsorption. This is very important clinically. In the treatment of hypercalcemia, volume expansion with normal saline, which decreases sodium reabsorption, effectively increases calcium excretion by the kidneys. Similarly, the inhibition of sodium reabsorption in the loop of Henle by loop diuretics such as furosemide increases urinary calcium excretion. The resultant

hypercalciuria is helpful in treating hypercalcemia, but chronic use of loop diuretics increases the risk of nephrocalcinosis and nephrolithiasis, especially when used in premature infants.

PTH is the principal regulator of urinary calcium excretion. PTH acts on the ascending limb of the loop of Henle and the distal nephron to increase calcium reabsorption. 1,25-dihydroxyvitamin D also stimulates calcium reabsorption in the distal nephron. Urinary calcium excretion increases in the absence of PTH. Urinary calcium excretion is also increased by growth hormone, metabolic acidosis, thyroid hormone, hyperphosphatemia, glucagon, osmotic diuretics, volume expansion, loop diuretics, and prolonged fasting. Even though urinary excretion of calcium is important, intestinal absorption is the primary site of regulation and, thus, there is usually minimal variation in urinary excretion despite variation in dietary intake.

Acute regulation of serum calcium depends on the large bone reservoir of calcium. PTH stimulates bone osteoclasts to dissolve bone and release calcium; it also increases the number of osteoclasts. In addition, PTH stimulates the 1a-hydroxylase in the kidney to convert 25-hydroxyvitamin D into 1,25-dihydroxyvitamin D. This active form of vitamin D acts on bone to increase calcium mobilization. The hormone calcitonin, produced by the parafollicular cells of the thyroid gland and secreted in response to hypercalcemia, inhibits the release of calcium from bone mediated by osteoclasts. Calcitonin also increases urinary excretion of calcium.

PTH and vitamin D have additional effects that are important for understanding the pathophysiology of calcium disorders. PTH increases urinary excretion of phosphate and bicarbonate. This compensates for the release of phosphate and base that occurs as a result of PTH-mediated bone resorption. Urinary phosphate wasting explains the hypophosphatemia often associated with hyperparathyroidism. 1,25-dihydroxyvitamin D participates in a negative feedback loop whereby PTH increases the synthesis of 1,25-dihydroxyvitamin D, which acts on the parathyroid gland to suppress PTH production. This is an important contributor to the secondary hyperparathyroidism of chronic renal failure. The failing kidneys cannot make adequate 1,25-dihydroxyvitamin D, which results in poor absorption of calcium. This leads to PTH synthesis caused by low serum calcium, and the lack of 1,25-dihydroxyvitamin D prevents its normal negative feedback on synthesis of PTH. 1,25-dihydroxyvitamin D also increases intestinal phosphate absorption, although phosphate absorption is not as dependent on vitamin D as calcium absorption.

HYPOCALCEMIA

Because of potentially severe symptoms such as laryngospasm and seizures, hypocalcemia needs to be identified and treated expeditiously. The ionized calcium concentration is low in true hypocalcemia. The total calcium concentration does not accurately predict the ionized calcium concentration in the patient with hypoalbuminemia. As previously discussed, the formula for correcting the total calcium concentration based on the concurrent albumin concentration is not always accurate, especially in the more critically ill child. Hence, the ionized calcium concentration should be determined in patients with suspected hypocalcemia when the patient is hypoalbuminemic and/or is critically ill.

Etiology and Pathophysiology.

There are many causes of hypocalcemia (Box 45–6). Hypocalcemia occurs most commonly in neonates. Hypocalcemia is one of the most common causes of neonatal seizures. This is usually due to early neonatal hypocalcemia,

Box 45.-6. Causes of Hypocalcemia

SPECIFIC CAUSES IN THE NEONATE

- Early neonatal hypocalcemia
- Late neonatal hypocalcemia
- Maternal hypercalcemia

HYPOPARATHYROIDISM

- DiGeorge syndrome (MIM* 188400)
- X-linked hypoparathyroidism (MIM 307700)
- Parathyroid hormone (PTH) gene mutations (MIM 168450)
- Calcium-sensing receptor mutation (MIM 601199)
- Autosomal recessive hypoparathyroidism with dysmorphic features (MIM 241410)
- HDR (or Barakat) syndrome (MIM 146255)
- Autoimmune polyglandular syndrome type I (MIM 240300)
- Kearns-Sayre syndrome (MIM 530000)
- Hemochromatosis
- Wilson disease (MIM 277900)

also called transient physiologic hypoparathyroidism. Early neonatal hypocalcemia occurs during the first 72?hr of life, usually before achieving a significant oral intake of milk. Serum calcium values correlate directly with gestational age, and less mature infants have a greater chance of developing hypocalcemia.

There are multiple mechanisms that account for early neonatal hypocalcemia. Even healthy term infants have a decrease in serum calcium concentration after birth, with the nadir occurring at approximately 24?hr. This is presumably due to the sudden disappearance of the transplacental delivery of calcium, an active process that maintains a higher calcium level in the fetus than in the mother. In addition, newborns may have a relative hypoparathyroidism, which has been attributed to the increased serum calcium level of the fetus, causing suppression of the parathyroid

gland. Newborns may also have a relative refractoriness of the target cells to parathyroid hormone.

Early hypocalcemia in neonates occurs most commonly in low birthweight infants, especially those with intrauterine growth retardation, in infants born of diabetic mothers, and in infants who have been subjected to prolonged, difficult deliveries (see Chapters 95 and 96). The incidence of hypocalcemia is inversely proportional to gestational age and birthweight. Because of the interruption of calcium transfer across the placenta, the rate of calcium delivery invariably decreases after birth. Calcium intake may be further decreased because the infant's small size or illness prevents normal feeding. Excessive secretion of calcitonin may be a contributing factor in persistent hypocalcemia of premature infants, particularly those stressed by anoxia. The incidence of hypocalcemia in prematurely born infants is extremely high, particularly in those with respiratory distress and those who have received intravenous sodium bicarbonate. Hypocalcemia should be suspected as a possible cause of convulsions in such neonates. Infants born of diabetic mothers have a high incidence of hypocalcemia, with a higher risk if the mothers have had poor metabolic control of their diabetes. Infants of diabetic mothers are more likely to be premature and have birth asphyxia. In addition, diabetes, by causing maternal magnesium depletion, may decrease transfer of magnesium to the fetus. The consequent hypomagnesemia in infants of diabetic mothers causes secondary hypoparathyroidism and hypocalcemia. Early preterm infants are often less symptomatic from hypocalcemia. This may be related to their lower serum albumin and their metabolic acidosis, both leading to an increase in the ionized calcium concentration because of less binding of calcium to albumin. Even though the hypocalcemia in premature or asphyxiated infants usually resolves in a few days, some infants of diabetic mothers have a more prolonged course.

Late hypocalcemia in neonates, much less common than early hypocalcemia, is due to intake of milk with a high content of phosphate. The onset of symptoms occurs most commonly during the first 5–10 days of life; clinical manifestations have occasionally appeared as late as 6 wk of age. The incidence of late neonatal hypocalcemia decreased dramatically when the phosphorus content of formula was reduced. It does not occur in breast-fed infants because of the lower phosphate content of breast milk compared to formula; breast milk has about 140?mg/L of phosphorus and current standard formula has at least twice as much phosphorus. The inappropriate use in a neonate of whole cow's milk, which has 956?mg/L of phosphorus, can cause hyperphosphatemia and secondary hypocalcemia. Late neonatal hypocalcemia most often occurs in otherwise healthy, full-term neonates. The intake of a high-phosphate food in a relatively large volume, combined with decreased renal phosphate excretion, leads to an elevated serum phosphorus level. The decreased renal phosphate excretion is due to the physiologically low GFR of the newborn and relatively high tubular reabsorption of phosphate. The elevated serum phosphorus level depresses the serum calcium level through

deposition of calcium phosphate in bone and possibly in other tissues. The normal physiologic response is an increased output of PTH, which stimulates calcium release from bone and urine phosphate excretion. This restores the normal serum levels of calcium and phosphorus. Infants with late neonatal hypocalcemia may have normal or elevated PTH, but the PTH response is relatively inadequate because the serum calcium is low. The immature parathyroid gland, in affected children, may not be able to respond appropriately. Alternatively, some of these infants may have an appropriate PTH response to hypocalcemia, but have end-organ resistance to PTH. This “transient pseudohypoparathyroidism” self-resolves.

Hypocalcemia may occur in infants born to mothers with hypercalcemia, which is commonly due to *hyperparathyroidism from a parathyroid adenoma*. The constant in utero suppression of the parathyroid gland can lead to prolonged hypoparathyroidism in the neonate, sometimes lasting for months. The infants usually develop tetany during the first 3 wk of life, but it may occur later if the infant is breast-fed. Often the mother is asymptomatic and the diagnosis depends on obtaining a maternal serum calcium level.

There are multiple causes of primary hypoparathyroidism (see Chapter 565). Along with hypocalcemia, hypoparathyroidism leads to hyperphosphatemia due to decreased renal excretion of phosphate. PTH levels are either low or undetectable, although inappropriately normal levels in the setting of hypocalcemia may occur in children with some residual PTH production. Because PTH and hypophosphatemia are the normal stimuli for the renal 1a-hydroxylase, 1,25-dihydroxyvitamin D levels are low.

In *DiGeorge syndrome* (also called velocardiofacial syndrome), most patients have a small deletion of chromosome 22 (see Chapter 115.1). It occasionally occurs in patients with a small deletion in chromosome 10. Along with a high incidence of congenital heart disease, these children may have facial anomalies, hypoplasia or aplasia of the parathyroid gland, and, rarely, severe immunodeficiency resulting from aplasia of the thymus. If hypocalcemia occurs in these patients, it is often transitory during the neonatal period, although it may be permanent, recur, or only appear later in life.

X-linked hypoparathyroidism is a rare disorder with unaffected female carriers. Affected boys have an absence of parathyroid tissue and present with hypocalcemia during the first 6 mo of life. Mutations in the PTH gene, with either autosomal recessive or autosomal dominant inheritance, are potential causes of hypoparathyroidism. One form of *autosomal dominant hypoparathyroidism* is secondary to an activating mutation of the calcium-sensing receptor. The parathyroid gland perceives a higher calcium concentration than actually exists; PTH levels are inappropriately normal for the degree of hypocalcemia. *Autosomal recessive hypoparathyroidism* with dysmorphic features is rare, with the only descriptions in Middle Eastern families, usually with consanguinity. **HDR syndrome,** an autosomal dominant disorder, is the combination of **h**ypoparathyroidism, nerve **d**eafness, and **r**enal dysplasia. It is due to a mutation in the GATA3 gene, which produces a zinc finger transcription factor. *Autoimmune polyglandular syndrome type I* is an autosomal recessive disorder, due to mutations in the autoimmune regulator (AIRE) gene, with the combination of hypoparathyroidism, Addison diseases, and mucocutaneous candidiasis, although most patients only have two of these three problems. Candidiasis usually precedes parathyroid gland dysfunction. Hypoparathyroidism, when it occurs, does not usually appear until after 5 yr of age in *Kearns-Sayre syndrome*, a mitochondrially inherited disorder. Copper overload in *Wilson disease* or iron overload in *hemochromatosis* may cause hypoparathyroidism. The iron overload may be secondary to multiple transfusions, as in patients with

thalassemia. Accidental removal of the parathyroid gland or disruption of its blood supply may occur after thyroid surgery or after neck surgery for non-thyroid cancer. Radioactive iodine ablation of the thyroid gland for Graves' disease may inadvertently damage the parathyroid gland.

Hypomagnesemia causes secondary hypoparathyroidism because an adequate serum magnesium concentration is necessary for normal release of PTH. In addition, magnesium appears to be important for a normal response to the actions of PTH. Hypomagnesemia causes target-organ resistance to PTH.

In *pseudohypoparathyroidism* there is adequate production of PTH, but a lack of response at the target organs (see Chapter 566). Patients have hypocalcemia, hyperphosphatemia, and low levels of 1,25-dihydroxyvitamin D. Most patients have a defect in the alpha-subunit of the stimulatory G protein that is necessary for signal transduction when PTH binds to its receptor. Administration of PTH to these patients fails to increase renal phosphate excretion or to increase serum calcium. Furthermore, there is no increase in urinary cAMP, as normally occurs as a result of G protein–mediated activation of adenylate cyclase after PTH binds to its receptor. The measurement of urinary cAMP after infusion of synthetic PTH is the diagnostic test of choice for establishing the diagnosis. Children with pseudohypoparathyroidism type 1A have the phenotypic features of Albright hereditary osteodystrophy, including short stature, stocky build, round face, and brachydactyly due to shortened metacarpals and metatarsals. Moderate mental retardation occurs in about 50% of these patients. Pseudohypoparathyroidism type 1B is identical to type 1A, except for the absence of the features of Albright hereditary osteodystrophy. This disease is also secondary to a defect in the stimulatory G protein, and patients have an impaired urinary cAMP response to synthetic cAMP. In pseudohypoparathyroidism type II, a rare and poorly described disorder, there is PTH resistance but a normal urinary cAMP response to PTH infusion.

In *vitamin D deficiency*, hypocalcemia is primarily the result of poor intestinal absorption of calcium. PTH levels are increased as a response to the inadequate calcium, and this initially prevents the development of frank hypocalcemia by causing release of calcium from bone, decreasing urinary losses of calcium, and upregulating the activity of the 1a-hydroxylase that converts 25-hydroxyvitamin D into the active form of vitamin D, 1,25-dihydroxyvitamin D. When these compensatory mechanisms are inadequate, hypocalcemia develops. Most children with inadequate vitamin D receive medical attention for rickets before developing hypocalcemia (see Chapter 44.10). Children with vitamin D deficiency have elevated serum levels of PTH, and, because of increased osteoclast activity, elevated serum levels of alkaline phosphatase. Serum phosphorus is usually low as a result of decreased intestinal absorption and increased urinary excretion secondary to the effect of PTH.

Vitamin D deficiency may be secondary to poor intake combined with inadequate exposure to ultraviolet light from the sun. In the United States, it is most common in African-American children who are breast-fed but do not receive vitamin D supplementation. Malabsorption of fat-soluble vitamins, including vitamin D, occurs with liver disease, gastrointestinal disease, and pancreatic insufficiency. Some patients with liver disease have an inability to convert vitamin D into 25-hydroxyvitamin D. Some medications, including the anticonvulsants phenobarbital and phenytoin, by increasing the activity of the P450 system in the liver, increase the metabolic degradation of vitamin D. Patients with vitamin D deficiency due to nutritional deficiency, malabsorption, or increased degradation have low levels of 25-hydroxyvitamin D. Because of upregulation of 1a-hydroxylase, levels of 1,25-dihydroxyvitamin D may be low, normal, or high. Children with vitamin D–dependent rickets type 1, an autosomal recessive disorder, have an absence of the kidney's 1a-hydroxylase, preventing conversion of 25-hydroxyvitamin into 1,25-dihydroxyvitamin D. These patients have normal levels of 25-hydroxyvitamin D but low levels of

1,25 dihydroxyvitamin D. In vitamin D–dependent rickets type 2, the vitamin D receptor is defective, preventing a normal physiologic response to 1,25-dihydroxyvitamin D. Thus, there is not a true deficiency; 1,25-dihydroxyvitamin D levels are typically elevated. Approximately 50% of children with this autosomal recessive disorder have alopecia. With chronic renal failure, there is a loss of activity of the 1a-hydroxylase in the kidney, leading to inadequate 1,25-dihydroxyvitamin D. In chronic renal failure, unlike the other causes of vitamin D deficiency, the patient has an elevated serum phosphorus as a result of decreased renal excretion.

In a variety of situations, there is a *redistribution of plasma calcium*, with a reduction in the ionized calcium concentration without any net loss of calcium from the body. A high serum phosphorus level produces a decrease in the serum calcium concentration. Calcium-phosphate complexes may deposit in tissues and the high phosphate in the blood leads to increased deposition of calcium and phosphate in bone. In addition, hyperphosphatemia inhibits the synthesis of 1,25-dihydroxyvitamin D, decreasing intestinal absorption of calcium. Hyperphosphatemia may be secondary to excessive intake, especially in the setting of decreased renal excretion due to renal insufficiency. Infants are vulnerable to hyperphosphatemia from excessive intake because of their lower GFR. Some laxatives and enemas contain high amounts of phosphorus, potentially producing severe hyperphosphatemia with secondary life-threatening hypocalcemia. The hyperphosphatemia in tumor lysis syndrome, which is due to release of intracellular phosphate, may cause hypocalcemia. In rhabdomyolysis, hypocalcemia is secondary to the combination of hyperphosphatemia due to release of intracellular phosphate and movement of calcium into the damaged muscle cells.

During *pancreatitis* there is release of pancreatic lipase, leading to breakdown of omental fat. The degraded fat then binds calcium and produces hypocalcemia. **Hungry bone syndrome** classically occurs after parathyroidectomy for hyperparathyroidism. In these patients, the sudden removal of the stimulus for osteoclast release of bone calcium causes calcium to move from the serum into bone because osteoblasts continue to deposit calcium into bone. This produces hypocalcemia and, by the same mechanism, hypophosphatemia and hypomagnesemia.

Citrate in transfused blood products complexes calcium. This causes a decrease in the ionized calcium concentration, potentially producing symptomatic hypocalcemia. The risk is highest with multiple transfusions or with exchange transfusions in neonates for hyperbilirubinemia or older children for sickle cell crises. The total

calcium concentration, because it includes calcium-citrate complexes, may be either normal or elevated.

The initial presentation in infants with *osteopetrosis*, characterized by very dense bone on x-ray, may be hypocalcemic seizures. Other manifestations include macrocephaly, hepatosplenomegaly, anemia, blindness, and deafness (see Chapter 687). Prompt diagnosis is essential because bone marrow transplantation, which is potentially curative, is best done before severe sequelae develop.

Patients with septic shock and intensive care unit patients in general are at increased risk for hypocalcemia, even though the mechanisms are unclear. Inadequate dietary calcium is an unusual cause of hypocalcemia in the United States, although it may occur with replacement of breast milk or formula with low-calcium milk substitutes in infants, poor calcium absorption due to high dietary phytate content, or inadequate calcium in total parenteral nutrition. In some intestinal disorders, such as celiac disease or intestinal lymphangiectasia, there may be inadequate absorption of both calcium and vitamin D.

Clinical Manifestations.

Symptoms of hypocalcemia are related to the degree of hypocalcemia and tend to be worse if the hypocalcemia develops acutely. Mild hypocalcemia is usually asymptomatic. The clinical manifestations of hypocalcemia are mostly due to neuromuscular irritability. Older children may complain of paresthesias, which are typically perioral or of the hands and feet. Tetany is the classic manifestation of hypocalcemia, and symptoms may include carpopedal spasm, laryngospasm, and seizures. Contractions of the muscles of the hands and feet produce carpopedal spasm, which can be quite painful. The wrists are flexed and the fingers extended, with the thumbs adducted over the palms. The feet are extended and adducted; the toes are plantar flexed. Laryngospasm is a spasmodic closure of the vocal cords. This produces inspiratory stridor and may be confused with laryngotracheitis. Severe laryngospasm may require intubation as a result of apnea and cyanosis. Seizures may be the first manifestation of hypocalcemia, especially in infants. The seizures, often brief but recurrent, are usually generalized but are occasionally localized. Patients usually do not lose consciousness between seizures, even though repeated seizures may induce a postictal state. Symptoms of tetany may be provoked in patients with hypocalcemia by hyperventilation, which by raising the pH causes calcium to bind to albumin, thereby lowering the ionized calcium concentration.

Newborn infants with hypocalcemia usually do not have carpopedal spasm. Along with seizures, manifestations in newborns may include irritability, muscular twitching, jitteriness, and tremors. Alternatively, newborns with hypocalcemia may have symptoms suggestive of sepsis, such as poor feeding, vomiting, and lethargy.

The consequences of long-standing hypocalcemia depend on the etiology. In children with inadequate vitamin D, there is concomitant hypophosphatemia and secondary hyperparathyroidism. These patients have inadequate bone mineralization, and consequently develop rickets (see Chapter 44.10). Rickets may also occur with severe dietary calcium deficiency. In hypoparathyroidism or pseudohypoparathyroidism, where hyperphosphatemia accompanies the hypocalcemia, there may be calcifications of the basal ganglia. In addition, calcifications of the lens may cause cataracts.

Chvostek and Trousseau signs may be elicited in patients with hypocalcemia. A positive Chvostek sign occurs if tapping the facial nerve anterior to the external auditory meatus elicits a twitch of the upper lip or entire mouth. This is not a very specific sign because it is positive in about 10% of patients without hypocalcemia. A false positive Chvostek sign is especially common in neonates. Trousseau sign is more specific, but quite uncomfortable to elicit and generally not an appropriate test in a child. A blood pressure cuff is inflated slightly above the systolic blood pressure for more than 3?min; carpopedal spasm occurs if hypocalcemia is present as a result of the ischemia of the motor nerves. The classic ECG change with hypocalcemia is a prolonged corrected QT interval. Other possible findings include a prolonged ST interval, peaked T waves, arrhythmias, and heart block. Hypocalcemia may impair cardiac contractility and decrease blood pressure. This is especially important in children with hypocalcemia due to sepsis.

Diagnosis.

The history in the child with hypocalcemia focuses on the dietary intake of calcium, phosphorus, and vitamin D. A family history of endocrine disorders or rickets is relevant because some causes of hypocalcemia are familial. In some patients, such as those with pancreatitis or tumor lysis syndrome, the clinical history provides the explanation for the hypocalcemia and extensive diagnostic testing is unnecessary. This also applies to children with sepsis or with multiorgan failure in an intensive care unit. Because hypocalcemia is so common in these settings, no work-up is usually necessary unless the child has disproportionate difficulties with hypocalcemia.

The history in early neonatal hypocalcemia is usually significant for prematurity, maternal diabetes, intrauterine growth

---

retardation, or a difficult birth. Early neonatal hypocalcemia is quite common, and most of these infants do not require an extensive work-up for unusual causes of hypocalcemia, unless the hypocalcemia is refractory to usual therapy or is prolonged. However, the nonspecific symptoms of neonatal hypocalcemia, including seizures and lethargy, often necessitate investigation for sepsis, intracranial bleeds, and meningitis. Late neonatal hypocalcemia is usually associated with hyperphosphatemia, and monitoring of the serum phosphorus helps guide therapy (see later text). A serum magnesium level is useful in both early and late neonatal hypocalcemia because hypomagnesemia may accompany the hypocalcemia and contribute to its pathogenesis. Treatment of the hypomagnesemia may be necessary for correction of the hypocalcemia. For infants with persistent hypocalcemia, a maternal history of hyperparathyroidism should be investigated, with laboratory testing of the mother for hypercalcemia because many mothers are asymptomatic. In addition, a chest roentgenogram should be obtained; the absence of a thymic shadow or findings suggestive of congenital heart disease may be seen in DiGeorge syndrome.

Except for early neonatal hypocalcemia, most children with hypocalcemia and no

clear etiology require a comprehensive evaluation. This includes children with late neonatal hypocalcemia, which is so unusual with current infant formula preparations that a work-up for other causes is necessary unless the history reveals excessive phosphorus intake. Initial laboratory testing includes measurement of the serum levels of phosphorus, alkaline phosphatase, magnesium, PTH, BUN, and creatinine. In addition, 1,25-dihydroxyvitamin D and 25-hydroxyvitamin D levels are helpful in differentiating the various etiologies of vitamin D deficiency. The 25-hydroxyvitamin D level is low in nutritional vitamin D deficiency, whether due to poor intake, lack of sun exposure, malabsorption, or excess metabolism. In vitamin D–dependent rickets type 1, the 25-hydroxyvitamin D level is normal, but the 1,25-dihydroxyvitamin D is low. In vitamin D–dependent rickets type 2, the 1,25-dihydroxyvitamin D level is elevated. In vitamin D deficiency, the serum phosphorus is usually low, unless the deficiency in 1,25-dihydroxyvitamin D is secondary to renal failure. This contrasts with the elevated serum phosphorus in children with hypoparathyroidism or pseudohypoparathyroidism. In addition, the alkaline phosphatase level is high with vitamin D deficiency and normal or low with hypoparathyroidism. A low or inappropriately normal PTH level in the presence of hypocalcemia is characteristic of hypoparathyroidism; the PTH level is elevated with pseudohypoparathyroidism. Children with hypomagnesemia may have an inappropriately low PTH level; a normal serum magnesium level eliminates hypomagnesemia as a cause of hypocalcemia.

Treatment.

For symptomatic hypocalcemia in neonates, calcium gluconate is given at a dose of 100–200?mg/kg (1–2?mL/kg of a 10% solution; 9–18?mg of elemental Ca/kg). This dose may be repeated every 6–8?hr until the calcium level stabilizes. Alternatively, calcium gluconate may be given as a constant intravenous infusion, with neonates typically requiring 500–750?mg/kg/24?hr of calcium gluconate. Ionized calcium levels should be monitored closely because of the risk of hypercalcemia. The intravenous calcium is gradually tapered while following serum calcium levels. The hypomagnesemia that sometimes accompanies early neonatal tetany is usually mild and transient; occasionally, it requires treatment before the hypocalcemia responds to therapy. With early neonatal hypocalcemia, the serum calcium level typically normalizes within 1–3 days. When feasible, neonates with previously symptomatic early hypocalcemia may transition to oral calcium supplementation, which is typically needed for about a week. Even though asymptomatic early hypocalcemia in premature infants usually resolves spontaneously, oral calcium supplementation, if possible, may prevent the need for intravenous therapy. For ill neonates who cannot tolerate enteral feedings, intravenous calcium is usually necessary.

Late neonatal hypocalcemia is usually at least partially secondary to concomitant hyperphosphatemia. Therapy attempts to lower the serum phosphorus level by decreasing phosphorus intake. Similac PM 60/40 is an infant formula with a low phosphorus content, but it has low calcium content so oral calcium supplementation is necessary. Alternatively, oral calcium can be added to conventional infant formula; calcium binds phosphorus in the lumen of the intestine, decreasing the amount of phosphorus that can be absorbed.

Liquid calcium preparations are available for oral dosing in neonates. The starting dose of calcium gluconate is 500–750?mg/kg/24?hr, divided into 4–6 doses. Calcium glubionate syrup is begun at a dose of 700–1000?mg/kg/24?hr, divided into 4–6 doses.

Beyond the neonatal period, 100–200?mg/kg of intravenous calcium gluconate over 5–10?min is an effective approach for symptomatic hypocalcemia. The adult dose of intravenous calcium gluconate is 1–3?g. One gram is 10?mL of a 10% solution and this supplies 94?mg of elemental calcium. Additional doses are given as necessary. Some patients require a continuous calcium drip, titrated to maintain the desired serum calcium level.

Once the symptoms of hypocalcemic tetany resolve with intravenous therapy, enteral calcium supplementation is usually appropriate. Liquid preparations of calcium carbonate (400?mg of elemental calcium/g), calcium glubionate (64?mg of elemental calcium/g) and calcium gluconate (90?mg of elemental calcium/g) are available. A typical starting dose of elemental calcium is 50?mg/kg/24?hr, usually divided into 3–4 doses. The adult starting dose is 1–3?g of elemental calcium per day. Chewable calcium carbonate is effective in older children. Titration of the dose of enteral calcium is based on serum calcium levels. For many conditions, vitamin D supplementation is also necessary (see later text). Calcium preparations bind with phosphorus in the intestinal lumen and decrease its absorption. This can be advantageous in hypocalcemic disorders that are associated with hyperphosphatemia, including renal failure, tumor lysis syndrome, and hypoparathyroidism. However, in other patients this may cause hypophosphatemia. Giving calcium supplements between meals reduces the phosphorus binding and may help to prevent hypophosphatemia.

Intravenous calcium should only be given with close monitoring. There is a significant risk of tissue necrosis and calcification if intravenous calcium extravasates; calcium cannot be given intramuscularly. A peripheral intravenous line that is infusing calcium must be observed carefully. Central access is preferred if possible. Patients receiving intravenous calcium should be on a cardiac monitor. High blood concentrations of calcium may inhibit the sinus node. This initially causes bradycardia, but can cause cardiac arrest. A gradual decrease or sudden slowing in the heart rate is an indication for stopping or decreasing the rate of a calcium infusion. ECG monitoring is especially important for patients on digoxin because intravenous calcium increases the risk of digitalis toxicity.

In certain situations, such as pancreatitis and rhabdomyolysis, complete correction of the hypocalcemia should be avoided because with resolution of the primary problem there is release of the complexed calcium and hypercalcemia may ensue. If acidemia is present, the hypocalcemia should, if possible, be corrected first. Acidemia increases the ionized calcium concentration by displacing calcium from albumin. The correction of the acidemia causes the ionized calcium concentration to decrease. In renal failure, dialysis using a high calcium dialysate helps to correct hypocalcemia while also correcting the metabolic acidosis. When hypomagnesemia is the etiology of the hypocalcemia, correction of the hypomagnesemia is necessary. In hungry bone syndrome, some patients may need supplemental phosphorus and magnesium, along with calcium.

Many patients with hypocalcemia require vitamin D supplementation. For children with deficiency secondary to poor intake, malabsorption, or increased metabolism, oral vitamin D is appropriate therapy. Correction of nutritional vitamin D deficiency typically requires about 5,000?IU/24?hr. Alternatively, a 1-day dose of 600,000?IU may be given. Most children with nutritional vitamin D deficiency do not need prolonged calcium supplementation, although they should receive a diet with adequate phosphorus and calcium. Children with malabsorption of vitamin D require much higher daily doses of vitamin D; 25,000 to 50,000?IU of vitamin D per day may be necessary. Severe malabsorption may necessitate intravenous vitamin D in total parenteral nutrition or intramuscular vitamin D. Children with renal failure, vitamin D–dependent rickets type 1, hypoparathyroidism, or pseudohypoparathyroidism do not appropriately convert 25-hydroxyvitamin D into 1,25-dihydroxyvitamin D. These children respond to 1,25-dihydroxyvitamin D (Rocaltrol). Starting doses range from 0.01– 0.08?µg/kg/24?hr. Adults normally require 0.25–1?µg/24?hr.

Long-term treatment of hypoparathyroidism and pseudohypoparathyroidism requires monitoring of serum calcium levels to avoid hypercalcemia. In addition, because there is a significant risk of hypercalciuria with the potential for nephrolithiasis and nephrocalcinosis, it is important to also monitor the urinary calcium. The use of a thiazide diuretic may help to decrease urinary calcium.

HYPERCALCEMIA

Hypercalcemia is frequently discovered incidentally on a routine chemistry profile. This is because hypercalcemia is an uncommon electrolyte disorder, and its clinical manifestations are fairly nonspecific. There are, however, some clinical situations in which hypercalcemia should be suspected.

As previously discussed, the ionized calcium concentration, not the total calcium concentration, is physiologically relevant. Hypercalcemia may go undetected in the patient with hypoalbuminemia and a “normal” total calcium concentration. The ionized calcium concentration is the gold standard for evaluating children with calcium disorders.

Etiology and Pathophysiology.

The regulation of serum calcium concentration is dependent on parathyroid hormone, vitamin D, appropriate calcium intake, and renal calcium excretion. Derangements in any of these systems can produce hypercalcemia. In addition, bone is a massive potential source of calcium, which, if inappropriately mobilized, produces hypercalcemia. A variety of different mechanisms may cause hypercalcemia (Box 45–7).

A variety of diseases may cause *primary hyperparathyroidism* (see Chapter 567). The excessive PTH causes hypercalcemia by increasing 1,25-dihydroxyvitamin D synthesis, releasing calcium from bone and decreasing urinary calcium excretion. There is hypophosphatemia due to PTH-mediated renal phosphate wasting. Sporadic adenomas are much more common in adults than in children. Adenomas may be part of a genetic disorder such as familial isolated hyperparathyroidism, multiple endocrine neoplasia type I, multiple endocrine neoplasia type II, or hyperparathyroidism-jaw tumor syndrome.

Neonatal hyperparathyroidism is a severe, life-threatening disorder. Most cases are due to an absence of functional calcium-sensing receptors in the parathyroid gland. Without functional sensors, the parathyroid gland is unable to monitor the extracellular calcium concentration. This leads to continued production of PTH despite increasing serum calcium levels. This is an autosomal recessive disorder, with both parents having one defective calcium sensor. The parents therefore have mild, benign hypercalcemia (see the later description of familial hypocalciuric hypercalcemia). Transient secondary neonatal hyperparathyroidism is a complication in neonates born to mothers with

hypocalcemia, usually due to hypoparathyroidism. The mother's hypocalcemia leads to fetal hypocalcemia and secondary hyperparathyroidism. This can cause poor fetal growth, bone demineralization, and even fractures. Some of these infants have hypercalcemia, which is occasionally the only manifestation. The hypercalcemia resolves over days to weeks as parathyroid gland function returns to normal.

Tertiary hyperparathyroidism occurs when prolonged secondary hyperparathyroidism progresses to either an autonomous parathyroid gland or a parathyroid adenoma. The exact mechanism is unknown, but is dependent on sustained hyperactivity of the parathyroid gland. In children, this most commonly occurs with chronic kidney failure due to inadequate 1,25-dihydroxyvitamin D. Tertiary hyperparathyroidism is also occasionally seen in children with X-linked hypophosphatemic rickets, wherein treatment with dietary phosphate decreases calcium absorption, which causes activation of the parathyroid gland. Parathyroidectomy is often necessary in tertiary hyperparathyroidism.

Extremely *high intake of vitamin D* can produce hypercalcemia. PTH levels are appropriately suppressed while the serum phosphorus level is elevated as a result of vitamin D's effect on intestinal absorption of phosphate and the lack of PTH to stimulate

renal phosphate excretion. The hypercalcemia of hypervitaminosis D typically

persists for weeks to months because of vitamin D's long half-life. Specific therapy includes discontinuation of vitamin D and a low calcium diet. Glucocorticoids are especially useful because they inhibit the action of vitamin D on both bone and intestines and decrease the levels of 1,25-dihydroxyvitamin D and 25-hydroxyvitamin D in the serum.

Subcutaneous fat necrosis is a disorder of the first few months of life (see Chapter 650). Infants are typically full-term and most have a history of birth asphyxia or trauma. The subcutaneous fat necrosis usually appears 1–2 wk after birth. Infants have hard nodules or plaques with overlying erythematous or purple skin. The most common sites are the cheeks, buttocks, back, and thighs. Skin biopsy shows fat necrosis and granulomatous infiltration with multinucleated giant cells. PTH levels are appropriately low. The hypercalcemia is believed to be due to excessive 1,25-dihydroxyvitamin D, which is probably produced by the macrophages infiltrating the areas of fat necrosis. This is presumably analogous to the situation in granulomatous diseases such as sarcoidosis (see later text).

Up to 40% of patients with *sarcoidosis* develop hypercalciuria, whereas a smaller percentage develop hypercalcemia. The mechanism is production of 1,25-dihydroxyvitamin D by pulmonary macrophages. These macrophages have 1-ahydroxylase, the enzyme that converts 25-hydroxyvitamin D into 1,25-dihydroxyvitamin D. Because the macrophages require 25-hydroxyvitamin D as a precursor to synthesize 1,25-dihydroxyvitamin D, the hypercalcemia may be intermittent, with an increased likelihood during the summer months (due to vitamin D production from sun exposure). Likewise, *oral vitamin D* can precipitate an episode of hypercalcemia. The hypercalciuria may produce nephrocalcinosis and nephrolithiasis. Treatment is restriction of vitamin D and sun exposure and corticosteroids. Hypercalcemia is less commonly caused by a number of other granulomatous diseases, such as tuberculosis and pulmonary fungal infections. Both non-Hodgkin lymphomas and Hodgkin disease have been associated with ectopic 1,25-dihydroxyvitamin D production.

Excessive calcium intake can cause hypercalcemia, especially if kidney impairment prevents renal excretion of calcium. While downregulation of 1,25-dihydroxyvitamin D does decrease calcium absorption, even without active vitamin D, there is passive intestinal absorption that is proportional to intake. With intravenous calcium, such as in total parenteral nutrition, there is no mechanism for downregulating absorption, and so the risk for iatrogenic hypercalcemia is higher.

Familial hypocalciuric hypercalcemia (FHH) is an autosomal dominant disorder caused by a mutation in the calcium-sensing receptor. Half the calcium-sensing receptors in the parathyroid glands are defective and, thus, the parathyroid glands do not receive an adequate signal at normal serum calcium concentrations. This results in increased PTH release at normal calcium concentrations. At the mildly elevated calcium concentrations in these patients, the remaining calcium sensors transmit enough signal that the PTH level decreases into the normal range, even though it is slightly increased in some patients. In addition, the deficiency in calcium-sensing receptors in the kidneys causes the renal tubules to avidly reabsorb calcium as a result of the perception that the serum calcium level is low. Urinary calcium levels are very low, with most patients having a urine calcium/creatinine ratio of less than 0.01?mg/mg. This is lower than in patients with primary hyperparathyroidism due to a parathyroid adenoma and is useful in differentiating these two entities. Other laboratory findings include a normal 1,25-dihydroxyvitamin D level, mild hypermagnesemia, and low-normal or decreased serum phosphorus. Because the serum calcium level is only mildly elevated, FHH is a benign condition; no treatment is necessary. Children who inherit a defective calcium-sensing receptor from each parent have severe neonatal hyperparathyroidism (see earlier text). Some neonates with FHH have skeletal changes of hyperparathyroidism, an elevated PTH, and mild to moderate hypercalcemia. Unlike those with the homozygous disorder, the hypercalcemia is not severe. The bone changes self-resolve, and parathyroidectomy is not necessary.

Thiazide diuretics decrease renal calcium excretion. In patients without another disorder affecting calcium metabolism, thiazide diuretics may cause a subtle increase in the serum calcium concentration, but they never cause hypercalcemia. Thiazide diuretics may precipitate hypercalcemia if there is a second mechanism present (e.g., hyperparathyroidism or high vitamin D intake).

Thyroid hormone directly stimulates bone resorption. Along with hypercalcemia, patients with hyperthyroidism have a decreased PTH level, increased serum phosphorus, and increased alkaline phosphatase. *Vitamin A intoxication* is another unusual cause of hypercalcemia, probably due to excessive bone resorption. Along with discontinuation of vitamin A and hydration, glucocorticoids are effective for treating the hypercalcemia.

Malignancies cause calcium release from bone via a variety of different mechanisms. Some tumors produce hypercalcemia by direct bone invasion and destruction. Parathyroid hormone related peptide (PTH-RP) has the same actions as PTH, but is normally only produced as a local hormone. Some tumor cells can produce PTH-RP in sufficient quantities that it has a systemic effect. Diagnosis requires analysis of blood for PTH-RP because it will not be detected using the assay for PTH. Patients with PTH-RP–induced hypercalcemia have a low serum phosphorus level, low PTH, and, unlike in patients with hyperparathyroidism, normal levels of 1,25-dihydroxyvitamin D. Rarely, tumors produce PTH. Yet another mechanism for malignancy associated hypercalcemia is the elaboration of factors that increase osteoclast resorption of bone.

Hypercalcemia from immobilization occurs in children with injuries such as leg fractures, burns, or spinal cord paralysis. The hypercalcemia is caused by bone resorption, which also explains the loss of bone mass that is associated with immobilization. The hypercalcemia usually occurs within 1–3 wk after leg fractures requiring traction. Following spinal cord injury the hypercalcemia commonly appears in 4–8 wk, but may appear earlier or months later. It is more common to detect isolated hypercalciuria, which may result in nephrocalcinosis, renal insufficiency, or kidney stones. PTH and 1,25-dihydroxyvitamin D are appropriately suppressed and the serum phosphorus level is often mildly elevated. Because of their higher rate of bone remodeling, children, especially adolescents, are affected more commonly than adults.

Some patients with *renal failure* develop bones that have lost their ability to take up calcium. This can be due to aluminum deposition in bone, although it is now more commonly seen without aluminum deposition and is called adynamic bone disease.

Williams syndrome is due to a deletion of a portion of chromosome 7 (see Chapters

97 and 420.5). This results in a contiguous gene syndrome, with multiple missing genes, and it is usually a new chromosomal deletion so the parents are unaffected. Most children have mild to moderate psychomotor retardation. Older children and adults have an outgoing "cocktail party" personality, but can also seem nervous. Facial features in infancy include periorbital fullness, broad nasal bridge, anteverted nares, long philtrum, open mouth, and full cheeks. Older children and adults have a different appearance, with a more elongated face, thicker lips, and a decrease in both the periorbital fullness and the full cheeks. Supravalvular aortic stenosis is the most common cardiovascular anomaly but it is only present in about one third of patients. Narrowing of the pulmonary arteries, the renal arteries, and the cerebral vasculature is also common. The cardiovascular abnormalities are probably due to the

disruption of the gene for elastin. The genetic and pathophysiologic explanation for the hypercalcemia is unknown. The hypercalcemia of Williams syndrome is usually diagnosed during infancy and resolves within a couple of years. It occasionally occurs in older children.

Low serum phosphorus can cause hypercalcemia. This may be due to the fact that hypophosphatemia stimulates the enzyme in the kidney (1 a-hydroxylase) that converts 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. This active form of vitamin D then stimulates calcium absorption in the gut. In addition, the deficiency of phosphate, which is needed for bone mineralization, prevents normal calcium deposition in the skeleton. This can occur in low-birthweight infants who are fed human milk, which has a low phosphate content. Hypercalcemia is a well described but unusual complication of a pheochromocytoma. Hypercalcemia is rarely associated with Addison disease, but the mechanism is unknown. The hypercalcemia resolves with glucocorticoid therapy.

Acute rhabdomyolysis causes hypocalcemia because of hyperphosphatemia, which leads to complexing of calcium and calcium deposition in injured tissues. This leads to appropriately high levels of PTH and 1,25-dihydroxyvitamin D. During the recovery phase, release of tissue calcium can lead to hypercalcemia. In addition, some patients have elevated levels of 1,25-dihydroxyvitamin D, which may further exacerbate the hypercalcemia. Avoiding overly aggressive treatment of the initial hypocalcemia may potentially prevent or lessen the subsequent hypercalcemia.

In *Jansen metaphyseal chondrodysplasia*, a defective PTH receptor sometimes causes hypercalcemia, along with a variety of other clinical manifestations (see Chapter 684). The PTH receptor is constitutively active and thus sends a signal as if PTH were present, which causes PTH effects in the kidney and bone. Therefore, despite a low PTH, there are similarities to hyperparathyroidism such as low-normal serum phosphorus, elevated 1,25-dihydroxyvitamin D, and elevated alkaline phosphatase.

In the *infantile form of hypophosphatasia*, the patients present during the first 6 mo of life with rickets and/or failure to thrive (see Chapter 694). Hypercalcemia is fairly common, and hypercalciuria can cause nephrocalcinosis. A low serum alkaline phosphatase is characteristic of this disorder. The serum phosphorus is normal.

Clinical Manifestations.

The signs and symptoms of hypercalcemia are related to the magnitude of the problem. Hypercalcemia is conventionally classified as mild (<12?mg/dL), moderate (12–15?mg/dL), or severe (>15?mg/dL). Many patients with mild or moderate hypercalcemia are asymptomatic, with the diagnosis resulting from an incidental laboratory test. Hypercalcemia has a number of common manifestations (Box 45–8). Infants often present with poor feeding, emesis, and failure to thrive. Severe hypercalcemia is occasionally fatal; ventricular arrhythmias are a serious concern. Psychiatric symptoms may include confusion, disorientation, depression, psychosis, and/or hallucinations. The polyuria of hypercalcemia is due to secondary nephrogenic diabetes insipidus (see Chapter 522). The high urinary water losses, especially when combined with emesis or decreased oral intake, leads to dehydration in a significant percentage of patients. This exacerbates the hypercalcemia and increases the risk of renal failure or kidney stones. In addition, the nephrogenic diabetes insipidus may cause hypernatremia.

The nephrocalcinosis is typically in the renal medulla, although cortical nephrocalcinosis is also seen. Both ultrasound, with hyperechogenicity, and CT scan may capture the nephrocalcinosis, although neither is sensitive enough to detect less severe cases.

Hypercalcemia can cause pancreatitis, which typically causes hypocalcemia. It is therefore important to monitor the serum

calcium as the pancreatitis resolves because the hypocalcemic effect of the pancreatitis may mask the true extent of the hypercalcemia.

Certain findings in patients with hypercalcemia are related to the underlying disease. Because PTH stimulates the kidney to excrete base, patients with hypercalcemia due to hyperparathyroidism classically have a mild metabolic acidosis. In contrast, most other patients have a metabolic alkalosis, which seems to be mediated by a combination of alkali release from bone and a direct effect of hypercalcemia that causes the kidney to hold onto base. PTH also causes renal phosphate wasting and hypophosphatemia. Other potential electrolyte complications of hypercalcemia include distal RTA, renal salt wasting, hypomagnesemia, and hypokalemia.

Diagnosis.

The history focuses on calcium intake, underlying diseases, renal function, and medications, including vitamins. The age of the patient is helpful. In infants, subcutaneous fat necrosis and Williams syndrome are important considerations; hypercalcemia may be the initial presentation of Williams syndrome. Laboratory evaluation should include electrolytes, BUN, creatinine, phosphorus, PTH, urinary calcium, urinary phosphorus, urinary creatinine (for calculation of the calcium/creatinine ratio and the tubular reabsorption of phosphorus), and a 25-hydroxyvitamin D level. In the setting of possible malignancy, a PTH-related peptide level might be helpful. Williams syndrome can be definitively diagnosed by fluorescent in situ hybridization using a probe for the deleted segment on chromosome 7.

Treatment.

The therapeutic approach depends on the severity of the hypercalcemia and the underlying etiology. Many patients with hypercalcemia are dehydrated as a result of polyuria from nephrogenic diabetes insipidus, poor oral intake, and/or vomiting. Rehydration lowers the serum calcium via dilution and corrects prerenal azotemia. The resultant increased urine output increases urinary calcium excretion. Urinary calcium excretion is increased by high urinary sodium excretion. Thus, the mainstay of treating hypercalcemia is aggressive therapy with normal saline, with the caveat that caution is mandatory to avoid fluid overload, especially in the setting of renal impairment or underlying cardiac disease. Urinary calcium excretion is further enhanced by the administration of a loop diuretic, which also helps to maintain adequate urinary volume given the high rate of intravenous saline. The loop diuretic is started once the

patient has been rehydrated. The high rates of intravenous fluid and urine output

combined with a loop diuretic can lead to a variety of electrolyte disturbances. Therefore, along with serum calcium, it is critical to monitor sodium, potassium, bicarbonate, and magnesium.

Normal saline, with or without a loop diuretic, is often adequate for treating mild or moderate hypercalcemia. More significant hypercalcemia often requires other therapies. Glucocorticoids decrease intestinal absorption of calcium by blocking the action of 1,25-dihydroxyvitamin D. There is also a decrease in levels of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D. The usual dose of prednisone is 1?mg/kg/24?hr. Glucocorticoids are especially effective when vitamin D is central in the pathogenesis of hypercalcemia, such as subcutaneous fat necrosis and vitamin D intoxication. A decrease in calcium, often dramatic, is frequently apparent within 24–72?hr. The direct tumoricidal effect of glucocorticoids may be useful in certain malignancies. In addition, glucocorticoids may block bone resorption, which is especially useful in some cancers. Glucocorticoids are especially effective in sarcoidosis because they also treat the underlying disease.

Calcitonin lowers calcium by inhibiting bone resorption. It also increases urinary calcium excretion, but this is a less important mechanism. The main advantages of calcitonin are limited side effects and a rapid onset of action, often within 2–4?hr. However, the decrease in calcium is usually less than 3?mg/dL, and patients can become resistant to therapy. Sensitivity to calcitonin may sometimes return by adding glucocorticoids or by changing to a regimen of periodic administration. Bisphosphonates are very effective; they inhibit bone resorption through their effects on osteoclasts. Hemodialysis, using a low or zero dialysate calcium, can rapidly lower serum calcium in patients with severe hypercalcemia. This therapy is especially useful in patients with either acute or chronic renal failure because urinary losses are inherently limited. Management of chronic hypercalcemia often requires a diet with decreased calcium and vitamin D.

Some etiologies of hypercalcemia require disease-specific therapy. Severe neonatal hyperparathyroidism is a surgical emergency, necessitating urgent parathyroidectomy. The hypercalcemia of sarcoidosis responds well to glucocorticoids, which both block intestinal action of vitamin D and treat the disease, decreasing the ectopic production of vitamin D by macrophages (see Chapter 155). Sarcoidosis also responds to ketoconazole or chloroquine. These medications inhibit the P450 system that is necessary to convert 25-hydroxyvitamin D into 1,25-dihydroxyvitamin D. Finally, sarcoidosis has also been treated with cellulose phosphate, which binds intestinal calcium, preventing its absorption. The hypercalcemia of thyrotoxicosis responds to treatment of the thyrotoxicosis. Similarly, treatment of Addison disease corrects the hypercalcemia.

45.6 Magnesium

MAGNESIUM METABOLISM

Body Content and Physiologic Function.

Magnesium is the fourth most common cation in the body and the third most common intracellular cation (see Fig. 45–3). Fifty percent to 60% of body magnesium is in bone, where it serves as a reservoir because one third is exchangeable, allowing movement to the extracellular space. Most intracellular magnesium is bound to proteins and other negatively charged molecules such as ATP; only about 25% is exchangeable. Because cells with higher metabolic rates have higher magnesium concentrations, most intracellular magnesium is present in muscle and liver.

The normal plasma magnesium concentration is 1.5–2.3?mg/dL (1.2–1.9?mEq/L; 0.62–0.94?mmol/L), with some variation between clinical laboratories. In the United States, serum magnesium is reported as mg/dL, but conversion from other units is necessary when reading the world literature or talking with colleagues from outside the United States (see Table 45–1). Infants have slightly higher plasma magnesium concentrations than older children and adults. Only 1% of body magnesium is extracellular (60% ionized; 15% complexed; 25% protein bound).

Magnesium is a necessary cofactor for hundreds of enzymes. It is important for membrane stabilization and nerve conduction. ATP and gaunosine triphosphate (GTP) need associated magnesium when they are used by ATPases, cyclases, and kinases.

Intake.

Between 30% and 50% of dietary magnesium is absorbed. Good dietary sources include green vegetables, cereals, nuts, meats, and hard water, although many foods contain magnesium. Human milk contains about 35?mg/L of magnesium; formula contains 40–70?mg/L. The small intestine is the major site of magnesium absorption, although the regulation of magnesium absorption is poorly understood. There is passive absorption, which permits high absorption in the presence of excessive intake. Absorption is diminished in the presence of substances that complex with magnesium (e.g., free fatty acids, fiber, phytate, phosphate, and oxalate); increased intestinal motility and calcium also decrease magnesium absorption. Vitamin D and PTH may enhance absorption, even though this effect is fairly limited. Intestinal absorption does increase when intake is decreased, possibly via a saturable active transport system. However, if there is no oral intake of magnesium, obligatory secretory losses prevent the complete elimination of intestinal losses.

Excretion.

Renal excretion is the principal regulator of magnesium balance. There is no defined hormonal regulatory system, even though PTH may increase tubular reabsorption. Approximately 15% of reabsorption occurs in the proximal tubule and 70% in the thick ascending limb (TAL) of the loop of Henle. Proximal reabsorption may be higher in neonates. High serum magnesium inhibits reabsorption in the TAL, suggesting that active transport is involved. Approximately 5–10% of filtered magnesium is reabsorbed in the distal tubule. Hypomagnesemia increases absorption in the TAL and the distal tubule.

HYPOMAGNESEMIA

Hypomagnesemia is relatively common in hospitalized patients, although most cases are asymptomatic. Detection requires a high index of suspicion because magnesium is not measured in most basic metabolic panels.

Etiology and Pathophysiology.

Gastrointestinal or renal losses are the major causes of hypomagnesemia (Box 45–9). *Diarrhea* has up to 200?mg/L of magnesium; gastric contents have only about 15?mg/L, but high losses can cause depletion. Steatorrhea causes magnesium loss as a result of the formation of magnesium-lipid salts; restriction of dietary fat can decrease losses.

Primary intestinal hypomagnesemia with secondary hypocalcemia, due to malabsorption of magnesium, is a rare autosomal recessive disorder, mapped to chromosome 9. The patients have seizures, tetany, tremor, or restlessness at 2–8 wk of life due to severe hypomagnesemia (0.2–0.8?mg/dL) and secondary hypocalcemia.

Renal losses may occur due to medications that are direct tubular toxins. Amphotericin frequently causes significant magnesium wasting and is typically associated with other tubular defects (especially potassium wasting). Cisplatin produces dramatic renal magnesium losses. Diuretics affect tubular handling of magnesium. Whereas loop diuretics cause a mild increase in magnesium excretion, thiazide diuretics have even less effect.

Potassium-sparing diuretics decrease magnesium losses. Osmotic agents, such as

mannitol, glucose in diabetes mellitus, or urea in the recovery phase of acute tubular necrosis, increase urinary magnesium losses. Intravenous fluid, by expanding the intravascular volume, decreases renal reabsorption of sodium and water, which impairs magnesium reabsorption. Hypercalcemia inhibits magnesium reabsorption in the loop of Henle, although this does not occur in the hypercalcemia due to familial hypercalcemic hypocalciuria or lithium.

There are a number of *rare genetic diseases* that cause renal magnesium loss. Gitelman and Bartter syndromes, autosomal recessive disorders, are the most common entities (see Chapter 523). Gitelman syndrome, which is due to a defect in the thiazide-sensitive Na-Cl co-transporter in the distal tubule, is almost always associated with hypomagnesemia. In Bartter syndrome, which can be caused by mutations in at least three different genes, hypomagnesemia is uncommon; when it does occur, it is usually associated with a defect in the basolateral chloride channel. In both disorders there is hypokalemic metabolic alkalosis, but in Gitelman syndrome there is hypocalciuria, and Bartter syndrome patients frequently have hypercalciuria and secondary nephrocalcinosis. In both disorders the hypomagnesemia is typically not severe and is asymptomatic, although tetany due to hypomagnesemia does occasionally occur.

Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (Michellis-Castrillo syndrome), an autosomal recessive disorder, is due to mutations in the gene for paracellin-1, which is located in the tight junctions of the thick ascending limb of the loop of Henle. Patients have severe renal wasting of magnesium and calcium with secondary hypomagnesemia and nephrocalcinosis; serum calcium levels are normal. Chronic renal failure frequently occurs during childhood. Other features include kidney stones, urinary tract infections, hematuria, increased PTH levels, tetany, seizures, hyperuricemia, ocular abnormalities, polyuria, and polydipsia. Autosomal recessive renal magnesium wasting without hypercalciuria is less commonly described and the genetic basis is unknown.

Autosomal dominant renal magnesium wasting is due to a dominant-negative mutation in the gene encoding the Na^+ ,K^+ -ATPase gamma-subunit and is associated with hypomagnesemia, increased urinary magnesium losses, hypocalciuria, and normocalcemia. Patients may present with seizures; most are asymptomatic despite serum magnesium levels of 0.8–1.5?mg/dL. Autosomal dominant hypoparathyroidism is caused by an activating mutation in the calcium-sensing receptor, which also senses magnesium levels in the kidney. The mutated receptor inappropriately perceives that magnesium and calcium levels are elevated, leading to urinary wasting. PTH levels are low despite hypocalcemia. Severe hypomagnesemia from renal losses is uncommonly present in mitochondrial disorders.

Poor intake is an unusual cause of hypomagnesemia, although it can be seen in children who are hospitalized and only receive intravenous fluids without magnesium. In **hungry bone syndrome,** which most frequently occurs after parathyroidectomy in patients with hyperparathyroidism, magnesium moves into bone as a result of accelerated bone formation. These patients usually have hypocalcemia and hypophosphatemia via the same mechanism. A similar mechanism can occur during the *refeeding phase of protein-calorie malnutrition* in children, with high magnesium utilization during cell growth depleting the patient's limited reserves. Insulin therapy stimulates uptake of magnesium by cells, and in *diabetic ketoacidosis*, in which total body magnesium is low because of osmotic losses, hypomagnesemia frequently occurs. In *pancreatitis*, there is saponification of magnesium and calcium in necrotic fat, causing both hypomagnesemia and hypocalcemia.

Transient hypomagnesemia in newborns, which is sometimes idiopathic, is more commonly seen in infants of diabetic mothers, presumably due to maternal depletion. Other maternal diseases that cause magnesium losses predispose infants to hypomagnesemia. Hypomagnesemia is more common in infants with intrauterine growth retardation. Hypomagnesemia may develop in newborn infants who require exchange transfusions because of magnesium removal by the citrate in banked blood (see Chapter 95).

Clinical Manifestations.

Hypomagnesemia causes secondary hypocalcemia by impairing the release of PTH by the parathyroid gland and through blunting the tissue response to PTH. Thus, hypomagnesemia is part of the differential diagnosis of hypocalcemia (see Box 45–6). This usually occurs only at magnesium levels less than 0.7?mg/dL. The dominant manifestations of hypomagnesemia are due to hypocalcemia: tetany, positive Chvostek and Trousseau signs, and seizures. However, with severe hypomagnesemia, these same signs and symptoms may be present despite normocalcemia. Persistent hypocalcemia due to hypomagnesemia is a rare cause of rickets.

Many causes of hypomagnesemia also result in hypokalemia. However, hypomagnesemia may produce renal potassium wasting and hypokalemia that only corrects with magnesium therapy. ECG changes with hypomagnesemia include flattening of the T wave and lengthening of the ST segment. Arrhythmias may occur, almost always in the setting of underlying heart disease.

Diagnosis.

The etiology of hypomagnesemia is often readily apparent from the clinical situation. The child should be assessed for gastrointestinal disease, adequate intake, and

---

kidney disease, with close attention to medications that may cause renal wasting. When the diagnosis is uncertain, an evaluation of urinary magnesium losses distinguishes between renal and nonrenal causes. The fractional excretion of magnesium is calculated via the following formula:

where FE_{Mg} = fractional excretion of magnesium; U_{Mg} = urinary magnesium concentration; P_{Cr} = plasma creatinine concentration; P_{Mg} = plasma magnesium concentration; U_{Cr} = urinary magnesium concentration. The plasma magnesium concentration is multiplied by 0.7 because approximately 30% is bound to albumin and not filtered at the glomerulus.

The fractional excretion of magnesium does not vary with age, but it does change based on the serum magnesium concentration. The fractional excretion ranges from 1 to 8% in children with normal magnesium levels. In the presence of hypomagnesemia due to extrarenal causes, it should be low due to renal conservation, typically less than 2%. The fractional excretion of magnesium is inappropriately elevated in the setting of renal wasting; values are almost always greater than 4% and frequently are greater than 10%. The measurement should not be evaluated during a magnesium infusion because the acute increase in serum magnesium increases urinary magnesium. Other approaches for evaluating urinary magnesium losses include calculation of 24-hr urinary magnesium losses and the ratio of urine magnesium to urine creatinine, both of which vary with age.

The genetic causes of renal magnesium loss are distinguished based on measurement of other serum and urinary electrolytes. Children with Gitelman syndrome and Bartter syndrome have hypokalemia and metabolic alkalosis.

Treatment.

Severe hypomagnesemia is treated with parenteral magnesium. Magnesium sulphate is given at a dose of 25–50?mg/kg (0.05–0.1?mL/kg of a 50% solution; 2.5–5.0?mg/kg of elemental magnesium). This is administered as a slow intravenous infusion, although it is frequently given intramuscularly in neonates. The rate of intravenous infusion should be slowed if patients experience diaphoresis, flushing, or a warm sensation. The dose is often repeated every 6?hr (every 8–12?hr in neonates) for a total of 2–3 doses before rechecking the plasma magnesium concentration. Lower doses are used in children with renal insufficiency.

Long-term therapy is usually given orally. Preparations include magnesium gluconate (5.4?mg elemental magnesium/100?mg), magnesium oxide (60?mg elemental magnesium/100?mg), and magnesium sulfate (10?mg elemental magnesium/100?mg). There are sustained-released preparations such as Slow-Mag (60?mg elemental magnesium/tablet) and Mag-Tab SR (84?mg elemental magnesium/tablet). Oral magnesium dosing should be divided to obviate cathartic side effects. Alternatives to oral magnesium are intramuscular injections and nighttime nasogastric infusion, both designed to minimize diarrhea. Magnesium supplementation must be used cautiously in the context of renal insufficiency (see later text).

HYPERMAGNESEMIA

Clinically significant hypermagnesemia is almost always secondary to excessive intake. It is unusual, except in neonates born to mothers who are receiving intravenous magnesium for preeclampsia or eclampsia (see Chapter 95).

Etiology and Pathophysiology.

There is no feedback mechanism to prevent magnesium absorption from the gastrointestinal tract. Magnesium is present in high amounts in certain laxatives, enemas, cathartics used to treat drug overdoses, and antacids. It is also usually present in total parenteral nutrition, and neonates may receive high amounts transplacentally if maternal levels are elevated. Usually the kidneys excrete excessive magnesium, but this ability is diminished in patients with chronic renal failure. In addition, neonates and young infants are vulnerable to excessive magnesium ingestion because of their reduced GFR. Most pediatric cases not related to maternal hypermagnesemia are in infants because of excessive use of antacids or laxatives. Mild hypermagnesemia may occur in chronic renal failure, familial hypocalciuric hypercalcemia, diabetic ketoacidosis, lithium ingestion, milk alkali syndrome, and tumor lysis syndrome. The hypermagnesemia in diabetic ketoacidosis occurs despite significant intracellular magnesium depletion due to urinary losses; hypomagnesemia often occurs following insulin treatment.

Clinical Manifestations.

Symptoms usually do not appear until the plasma magnesium is more than 4.5?mg/dL. Hypermagnesemia inhibits acetylcholine release at the neuromuscular junction, producing hypotonia, hyporeflexia, and weakness; paralysis occurs at high concentrations. Direct central nervous system depression causes lethargy and sleepiness; infants have a poor suck. Elevated magnesium is associated with hypotension because of vascular dilation, which also causes flushing. Hypotension can be profound at higher concentrations due to a direct effect on cardiac function. ECG changes include prolonged PR, QRS, and QT intervals. Severe hypermagnesemia (>15?mg/dL) causes complete heart block and cardiac arrest. Other manifestations of hypermagnesemia include nausea, vomiting, and hypocalcemia.

Diagnosis.

Except for the case of the neonate with transplacental exposure, a high index of suspicion and a good history are necessary to make the diagnosis. Prevention is essential; magnesium-containing compounds should be used judiciously in children with renal insufficiency.

Treatment.

Most patients with normal renal function rapidly clear excessive magnesium. Intravenous hydration and loop diuretics can accelerate this process. In severe cases, especially with underlying renal insufficiency, dialysis may be necessary. Hemodialysis works faster than peritoneal dialysis. Exchange transfusion is another option in newborn infants. Supportive care includes monitoring of cardiorespiratory status, fluids, and, if necessary, pressors for hypotension and electrolyte monitoring. In acute emergencies, especially in the context of severe cardiac manifestations, 100?mg/kg of intravenous calcium gluconate is transiently effective.

45.7 Phosphorus

Approximately two thirds of plasma phosphorus is in phospholipids, but these compounds are insoluble in acid and are not measured by clinical laboratories. It is the phosphorus content of plasma phosphate that is determined. The result is reported as either phosphate or phosphorus, although even when the term *phosphate* is used, it is actually the phosphorus concentration that is measured and reported. The end result is that *phosphate* and *phosphorus* are often used interchangeably. The term *phosphorus* is preferred when referring to the plasma concentration. Conversion from the units used in the United Stages (mg/dL) to mmol/L is straightforward (see Table 45–1)

PHOSPHORUS METABOLISM

Body Content and Physiologic Function.

Most phosphorus is in bone or is intracellular, with less than 1% in plasma. At a physiologic pH, there are monovalent and divalent forms of phosphate because the pK of these forms is 6.8. Approximately 80% is divalent and the remainder is monovalent at a pH of 7.4. A small percentage of plasma phosphate, about 15%, is protein bound.

The remainder can be filtered by the glomerulus, with most existing as free phosphate and a small percentage complexed with calcium, magnesium, or sodium. Phosphate is the most plentiful intracellular anion, although the majority is part of a larger compound (e.g., ATP).

The phosphorus concentration varies with age more than any other electrolyte (Table 45–2). The teleologic explanation for the high concentration during childhood is the need for phosphorus to facilitate growth. There is diurnal variation in the plasma phosphorus concentration, with the peak during sleep.

Phosphorus, as a component of ATP and other trinucleotides, is critical for cellular energy metabolism. It is necessary for nucleic acid synthesis and it is a component of cell membranes and other structures. Along with calcium, phosphorus is an essential component of bone, and it is necessary for skeletal mineralization. There is a significant need for a net positive phosphorus balance during growth, with the

growing skeleton especially vulnerable to deficiency.

Intake.

Phosphorus is readily available in food. Milk and milk products are the best sources of phosphorus, but high concentrations are present in meat and fish. Vegetables have more phosphorus than fruits and grains. Gastrointestinal absorption is fairly proportional to intake, with about two thirds of intake being absorbed, even including a small amount that is secreted. Absorption, almost exclusively in the small intestine, occurs via a paracellular diffusive process and a vitamin D–regulated transcellular pathway. However, the impact of the change in phosphorus absorption caused by vitamin D is relatively small compared to the effect of variations in phosphorus intake.

Excretion.

Despite the wide variation in phosphorus absorption dictated by oral intake, excretion matches intake, except for the needs for growth. The kidney is the principal regulator of phosphorus balance, which is mostly determined by intrarenal mechanisms. However, a number of hormones affect phosphorus excretion, although phosphorus homeostasis is not their main function.

About 90% of plasma phosphate is filtered at the glomerulus, although there is some variation based on plasma phosphorus and calcium concentrations. There is no significant secretion of phosphate along the nephron. Reabsorption of phosphate occurs mostly in the proximal tubule, even though a small amount of phosphate can be reabsorbed in the distal tubule. Normally about 85% of the filtered load is reabsorbed. The transport of phosphate from the tubular lumen into the cells of the proximal tubule is coupled with the transport of sodium down its chemical gradient. A sodium/phosphate co-transporter mediates the uptake of phosphate into the cells of the proximal tubule.

The dietary phosphorus determines the amount of phosphate reabsorbed by the nephron. There are both acute and chronic changes in phosphate reabsorption based on intake. Most of these changes appear to be mediated by intrarenal mechanisms that are independent of regulatory hormones. PTH, which is secreted in response to low plasma calcium, decreases reabsorption of phosphate, increasing urinary phosphate. This appears to have a minimal effect during normal physiologic variation in PTH levels. However, this does have an impact in the setting of pathologic changes in PTH synthesis (see later text).

TABLE 45.7-2 -- **Serum Phosphorus During Childhood**

Age	Phosphorus
0–5 days	4.8–8.2?mg/dL
1–3 years	3.8–6.5?mg/dL
4–11 years	3.7–5.6?mg/dL
12–15 years	2.9–5.4?mg/dL
16–19 years	2.7–4.7?mg/dL

Low plasma phosphorus stimulates the 1-ahydroxylase in the kidney that converts 25-vitamin D to 1,25-vitamin D (calcitriol). Calcitriol increases intestinal absorption of phosphorus and is necessary for maximal renal reabsorption of phosphate. The effect of a change in calcitriol on urinary phosphate is only significant when the level of calcitriol was initially low, arguing against a role for calcitriol in nonpathologic conditions.

A humoral mediator called *phosphatonin* inhibits renal reabsorption of phosphorus, causing both phosphaturia and hypophosphatemia in a variety of pathologic conditions. In autosomal dominant hypophosphatemic rickets, fibroblast growth factor type 23 has been identified as the phosphatonin. In X-linked hypophosphatemia rickets there is an absence of an endopeptidase that is believed to cleave a phosphatonin. The role of phosphatonins in normal physiology is not clear.

HYPOPHOSPHATEMIA

Because of the wide variation in normal plasma phosphorus, the definition of hypophosphatemia is age-dependent (see Table 45–2). The range reported on a laboratory report may be based on adult normal values and, therefore, may be misleading in children. For example, a serum phosphorus of 3?mg/dL, a normal value in an adult, is clinically significant hypophosphatemia in an infant.

The plasma phosphorus does not always reflect the total body stores because only 1% of phosphorus is extracellular. Thus, a child may have significant phosphorus deficiency despite a normal plasma phosphorus concentration. This is especially common in conditions in which there is a shift of phosphorus from the intracellular space (see later text).

Etiology and Pathophysiology.

A variety of mechanisms cause hypophosphatemia (Box 45–10). A transcellular shift of phosphorus into cells occurs with processes that stimulate cellular utilization of phosphorus (e.g., glycolysis). Usually this only causes a minor, transient decrease in plasma phosphorus, but if intracellular phosphorus deficiency is present, the plasma phosphorus can decrease significantly, producing symptoms of acute hypophosphatemia. Glucose infusion stimulates insulin release, which leads to entry of glucose and phosphorus into cells. Phosphorus is then used during glycolysis and other metabolic processes. A similar phenomenon can occur during the treatment of diabetic ketoacidosis, and these patients are typically phosphorus depleted due to urinary phosphorus losses. Refeeding of patients with protein-calorie malnutrition causes anabolism, which leads to significant cellular demand for phosphorus. The increased phosphorus uptake for incorporation into newly synthesized compounds containing phosphorus leads to hypophosphatemia, which can be severe and symptomatic. Refeeding hypophosphatemia in children occurs frequently during therapy of severe anorexia nervosa. It can occur during treatment of children with malnutrition due to any cause, including cystic fibrosis, Crohn disease, burns, neglect, chronic infection, or famine. Hypophosphatemia usually occurs within the

first 5 days of refeeding, and is prevented by a gradual increase in nutrition with appropriate supplementation (see Chapter 42.2). Total parenteral nutrition without adequate phosphorus can cause hypophosphatemia.

Phosphorus moves into the intracellular space during a respiratory alkalosis, which may occur as a result of an anxiety attack or in a variety of ill, hospitalized patients due to pain, sepsis, hepatic coma, or salicylate intoxication. The same transcellular shift of phosphorus takes place during recovery from a respiratory acidosis. An acute decrease in the carbon dioxide concentration, by increasing the intracellular pH, stimulates glycolysis, leading to intracellular utilization of phosphorus and hypophosphatemia. Because a metabolic alkalosis has less effect on the intracellular pH (carbon dioxide diffuses across cell membranes much faster than bicarbonate), there is minimal transcellular phosphorus movement with a metabolic alkalosis.

Tumors that grow rapidly, such as leukemia and lymphoma, can lead to a significant phosphorus utilization and hypophosphatemia. A similar phenomenon may occur during the hematopoietic reconstitution that follows a bone marrow transplantation. In hungry bone syndrome, there is avid bone uptake of phosphorus, along with calcium and magnesium, which can produce plasma deficiency of all three ions. Hungry bone syndrome is most common after parathyroidectomy for hyperparathyroidism because the stimulus for bone dissolution is acutely removed, but bone synthesis continues.

Nutritional phosphorus deficiency is unusual because most foods contain phosphorus. However, infants are especially susceptible because of their high demand for phosphorus to support growth, especially of the skeleton. Premature infants have particularly rapid skeletal growth, and can develop phosphorus deficiency and rickets if fed human milk or standard formula. There is also a relative deficiency of calcium. The provision of additional calcium and phosphorus, using breast milk fortifier or special premature infant formula, prevents this complication. Phosphorus deficiency, sometimes with concomitant calcium and vitamin D deficiency, occurs in infants who are not given enough milk or receive a milk substitute that is nutritionally inadequate.

Antacids containing aluminum hydroxide, such as Maalox and Mylanta, bind dietary phosphorus and secreted phosphorus, preventing absorption. This can cause phosphorus deficiency and rickets in growing children. A similar mechanism causes hypophosphatemia in patients who are overtreated for hyperphosphatemia with phosphorus binders. In children with kidney failure, the addition of dialysis to phosphorus binders increases the risk of iatrogenic hypophosphatemia in these normally hyperphosphatemic patients. This complication, more common in infants, can worsen renal osteodystrophy.

Excessive renal losses of phosphorus occur in a variety of inherited and acquired disorders. Because PTH inhibits the reabsorption of phosphorus in the proximal tubule, hyperparathyroidism causes hypophosphatemia (see Chapter 567). The dominant clinical manifestation, however, is hypercalcemia and the hypophosphatemia is usually asymptomatic. The phosphorus level in hyperparathyroidism is not extremely low and there is no continued loss of phosphorus because a new steady-state is achieved at the lower plasma phosphorus level. Renal excretion, therefore, does not chronically exceed intake. There are occasional malignancies that produce PTH-related peptide, which has the same actions as PTH and causes hypophosphatemia and hypercalcemia.

In X-linked hypophosphatemic rickets, there is urinary wasting of phosphorus and hypophosphatemia (see Chapter 696). Even though transmitted on the X chromosome, the disorder affects both males and female carriers, behaving more like an autosomal dominant disorder. Hypophosphatemia normally stimulates synthesis of 1,25 vitamin D, which should, therefore, be elevated when the serum phosphorus is low, but these patients have either low or inappropriately normal levels, and this defect contributes to the pathogenesis of the disease in that 1,25-vitamin D enhances renal retention and gastrointestinal absorption of phosphorus.

Tumor-induced osteomalacia is a rare disorder that clinically resembles X-linked hypophosphatemic rickets, except it is not hereditary (see Chapter 698). Along with renal phosphorus wasting, the 1,25-vitamin D levels are inappropriately low. This disorder is mediated by a humoral factor or factors, called *phosphatonins*, which are secreted by some mesenchymal tumors. Fibroblast growth factor type 23 is the phosphatonin in some of these tumors. Tumor resection is curative. This condition has occasionally been seen in patients with epidermal nevus syndrome, neurofibromatosis, and fibrous dysplasia.

Autosomal dominant hypophosphatemic rickets is due to a mutation that prevents the degradation of fibroblast growth factor type 23. High levels of this phosphatonin lead to renal phosphorus wasting, hypophosphatemia, inappropriately normal 1,25-vitamin D levels, and rickets. Fanconi syndrome is a generalized defect in the proximal tubule leading to urinary wasting of bicarbonate, phosphorus, amino acids, uric acid, and glucose (see Chapter 521). The clinical sequelae are due to the metabolic acidosis and the hypophosphatemia. In children, an underlying genetic disease, most commonly cystinosis, often causes Fanconi syndrome, but it can be secondary to a variety of toxins and acquired diseases. Some patients have an incomplete Fanconi syndrome, and phosphorus wasting may be one of the manifestations. The hypophosphatemia of Fanconi syndrome is generally associated with rickets and does not usually cause symptomatic acute hypophosphatemia.

Dent disease, an X-linked disorder resulting from a defective chloride channel, can cause renal phosphorus wasting and hypophosphatemia, although this is not present in most cases. Other possible manifestations of Dent disease include tubular proteinuria, hypercalciuria, nephrolithiasis, rickets, and chronic renal failure. Hypophosphatemic rickets with hypercalciuria is a rare disorder, principally described in kindreds from the Middle East.

Metabolic acidosis inhibits reabsorption of phosphorus in the proximal tubule. In addition, metabolic acidosis causes a transcellular shift of phosphorus out of cells because of intracellular catabolism. This released phosphorus is subsequently lost in the urine, leading to significant phosphorus depletion, even though the plasma phosphorus may be normal. This classically occurs in diabetic ketoacidosis in which renal phosphorus loss is further increased by the osmotic diuresis. With correction of the

metabolic acidosis and the administration of insulin, both of which cause a transcellular movement of phosphorus into cells, there is a marked decrease in the plasma phosphorus.

Volume expansion from any cause, such as hyperaldosteronism or SIADH, inhibits reabsorption of phosphorus in the proximal tubule. This also occurs with high rates of intravenous fluids. Thiazide and loop diuretics can increase renal phosphorus excretion, but this is seldom clinically significant. Glycosuria and glucocorticoids inhibit renal conservation of phosphorus. Hypophosphatemia is common after kidney transplantation due to urinary phosphorus losses. Possible explanations include pre-existing secondary hyperparathyroidism from chronic renal failure, glucocorticoid therapy, and upregulation of phosphatonins before transplantation. The hypophosphatemia usually resolves in a few months.

Both acquired and genetic causes of vitamin D deficiency are associated with hypophosphatemia (see Chapters 44.10 and 697). The pathogenesis is multifactorial. Vitamin D deficiency, by impairing intestinal calcium absorption, causes secondary hyperparathyroidism that leads to increased urinary phosphorus wasting. An absence of vitamin D decreases intestinal absorption of phosphorus and directly decreases renal reabsorption of phosphorus. The dominant clinical manifestation is rickets, although some patients have muscle weakness that may be related to phosphorus deficiency.

Alcoholism is the most common cause of severe hypophosphatemia in adults. Fortunately, many of the risk factors that predispose adult alcoholics to hypophosphatemia are not usually present in adolescents (e.g., malnutrition, antacid abuse, recurrent episodes of diabetic ketoacidosis). Hypophosphatemia often occurs in sepsis, even though the mechanism is not clear. Aggressive, protracted hemodialysis, as might be used for treatment of methanol or ethylene glycol ingestions, can cause hypophosphatemia.

Clinical Manifestations.

There are acute and chronic manifestations of hypophosphatemia. Rickets occurs in children with long-term phosphorus deficiency. The clinical features of rickets are described in Chapter 44.10 . With phosphorus deficiency, there is inadequate hydroxyapatite, preventing mineralization of osteoid, the organic matrix of bone. Osteomalacia is the general term for poorly mineralized bone; rickets is osteomalacia of the growth plates and can only occur in growing children. Older children and adults with chronic phosphorus deficiency develop isolated osteomalacia. Isolated phosphorus deficiency can cause rickets, although many children with rickets and hypophosphatemia have other pathogenic mechanisms contributing to the rickets. For example, children with vitamin D–deficiency rickets, who frequently have hypophosphatemia, also have inadequate calcium absorption and secondary hyperparathyroidism. In Fanconi syndrome the concurrent metabolic acidosis may contribute to the development of rickets.

Severe hypophosphatemia, typically levels less than 1–1.5?mg/dL, may affect every organ in the body because phosphorus has a critical role in maintaining adequate cellular energy. Phosphorus is a component of ATP and is necessary for glycolysis. With inadequate phosphorus, red blood cell 2,3-diphosphoglycerate levels decrease, impairing release of oxygen to the tissues. Severe hypophosphatemia can cause hemolysis and dysfunction of white cells and platelets. Chronic hypophosphatemia causes proximal muscle weakness and atrophy. In the intensive care unit, phosphorus deficiency may slow weaning from the ventilator or cause acute respiratory failure. Rhabdomyolysis is the most common complication of acute hypophosphatemia, usually in the setting of an acute transcellular shift of phosphorus into cells in a child with chronic phosphorus depletion (e.g., anorexia nervosa). The rhabdomyolysis is actually somewhat protective in that there is cellular release of phosphorus. Other manifestations of severe hypophosphatemia include cardiac dysfunction and neurologic symptoms such as tremor, paresthesia, ataxia, seizures, and coma.

Diagnosis.

The history and basic laboratory evaluation often suggest the etiology of hypophosphatemia. The history should investigate nutrition, medications, and familial disease. Hypophosphatemia and rickets in an otherwise healthy young child suggests a genetic defect in renal phosphorus conservation, Fanconi syndrome, inappropriate use of antacids, poor nutrition, vitamin D deficiency, or a genetic defect in vitamin D metabolism. In Fanconi syndrome, there is usually a metabolic acidosis, glucosuria, aminoaciduria, and a low plasma uric acid. Measurement of 25-vitamin D and 1,25-vitamin D, calcium, and PTH differentiates the various vitamin D deficiency disorders and X-linked hypophosphatemic rickets. Hyperparathyroidism is easily distinguished by the presence of elevated plasma PTH and calcium levels.

Treatment.

The plasma phosphorus level, the presence of symptoms, the likelihood of chronic depletion, and the presence of ongoing losses dictate the approach to therapy. Mild hypophosphatemia does not require treatment unless the clinical situation suggests that chronic phosphorus depletion is present or ongoing losses are occurring. Oral phosphorus can cause diarrhea so the doses should be divided. Intravenous therapy is effective in patients who have severe deficiency or cannot tolerate oral medications. Intravenous phosphorus is available as either sodium phosphorus or potassium phosphorus, with the choice usually based on the patient's plasma potassium level. The oral preparations of phosphorus are available with various ratios of sodium and potassium. This is an important consideration because some patients may not tolerate the potassium load while the supplemental potassium may be helpful in diseases such as Fanconi syndrome or malnutrition.

Increasing dietary phosphorus is the only intervention needed in infants with inadequate intake. Other patients may also benefit from increased dietary phosphorus, usually dairy products. Phosphorus-binding antacids should be discontinued in patients with hypophosphatemia. Certain diseases require specific therapy. For example, vitamin D supplementation, not phosphorus, is the principal therapy in nutritional vitamin D deficiency. X-linked hypophosphatemic rickets is usually treated with a combination of 1,25-vitamin D and oral phosphorus.

HYPERPHOSPHATEMIA

Etiology and Pathophysiology.

Renal insufficiency is the most common cause of hyperphosphatemia, with the severity proportional to the degree of kidney impairment. This occurs because the gastrointestinal absorption of the large dietary intake of phosphorus is unregulated, and the kidneys normally excrete this phosphorus. As renal function deteriorates, decreased reabsorption of phosphorus, partially mediated by increased PTH levels, is able to compensate. When kidney function is less than one third of normal, hyperphosphatemia usually develops, even though dietary intake of phosphorus does have a significant modulatory effect. Many of the other causes of hyperphosphatemia are more likely to develop in the setting of renal insufficiency (Box 45–11).

Cellular content of phosphorus is high relative to the plasma phosphorus, and cell lysis can release substantial phosphorus. This is the etiology of hyperphosphatemia in tumor lysis syndrome, rhabdomyolysis, and acute hemolysis. These disorders have concomitant potassium release and the risk of hyperkalemia. Additional features of tumor lysis and rhabdomyolysis are hyperuricemia and hypocalcemia, whereas an indirect hyperbilirubinemia and elevated lactate dehydrogenase (LDH) are often present with hemolysis. An elevated creatinine phosphokinase (CPK) is suggestive of rhabdomyolysis. During lactic

acidosis or diabetic ketoacidosis, there is a decreased utilization of phosphorus by cells and phosphorus shifts into the extracellular space. This problem reverses when

the underlying problem is corrected, and, especially with diabetic ketoacidosis, patients subsequently become hypophosphatemic as a result of previous renal phosphorus loss.

Excessive intake of phosphorus is especially dangerous in children with renal insufficiency. Neonates are at risk because renal function is normally reduced during the first few months of life. In addition, they may erroneously be given doses of phosphorus that are meant for an older child or adult. Infants fed cow's milk, which has higher phosphorus content than breast milk or formula, may develop hyperphosphatemia. Fleet enemas have a high amount of phosphorus, which can be absorbed, especially if there is an ileus. Infants and children with Hirschsprung disease are especially vulnerable. There is often associated hypernatremia due to sodium absorption and water loss from diarrhea. Sodium phosphorus laxatives may cause hyperphosphatemia if the dose is excessive or renal insufficiency is present. Hyperphosphatemia occurs in children who receive overly aggressive treatment for hypophosphatemia. Vitamin D intoxication causes excessive gastrointestinal absorption of both calcium and phosphorus, and the suppression of PTH by hypercalcemia decreases renal phosphorus excretion.

The absence of PTH in hypoparathyroidism or PTH responsiveness in pseudohypoparathyroidism causes hyperphosphatemia because of increased reabsorption of phosphorus in the proximal tubule of the kidney (see Chapters 565 and 566). The associated hypocalcemia is responsible for the clinical symptoms. The hyperphosphatemia in hyperthyroidism or acromegaly is usually minor. It is secondary to increased reabsorption of phosphorus in the proximal tubule due to the actions of thyroxine or growth hormone. Excessive thyroxine can also cause bone resorption, which may contribute to the hyperphosphatemia and cause hypercalcemia. **Tumoral calcinosis** with hyperphosphatemia is a rare autosomal recessive disorder with heterotopic calcification, predominantly affecting black adolescents.

Clinical Manifestations.

The principal clinical consequences of hyperphosphatemia are hypocalcemia and systemic calcification. The hypocalcemia is probably due to tissue deposition of calcium-phosphorus salt, inhibition of 1,25-vitamin D production, and decreased bone resorption. Symptomatic hypocalcemia is most likely to occur when the phosphorus increases rapidly or when diseases predisposing to hypocalcemia are present (e.g., chronic renal failure, rhabdomyolysis). Systemic calcification occurs because the solubility of phosphorus and calcium in the plasma is exceeded. This is believed to happen when the plasma calcium × plasma phosphorus, both measured in mg/dL, is more than 70. Clinically, this is often apparent in the conjunctiva, where it manifests as injection. More ominous manifestations are hypoxia from pulmonary calcification and renal failure from nephrocalcinosis.

Diagnosis.

The plasma creatinine and BUN should be assessed in any patient with hyperphosphatemia. The history should focus on intake of phosphorus and the presence of chronic diseases that may cause hyperphosphatemia. Measurement of potassium, uric acid, calcium, LDH, bilirubin, and CPK may be indicated if rhabdomyolysis, tumor lysis, or hemolysis is suspected. With mild hyperphosphatemia and significant hypocalcemia, measurement of the serum PTH level distinguishes between hypoparathyroidism and pseudohypoparathyroidism.

Treatment.

The treatment of acute hyperphosphatemia depends on the severity and etiology of the hyperphosphatemia. Mild hyperphosphatemia in a patient with reasonable renal function spontaneously resolves; this action can be accelerated by dietary phosphorus restriction. If kidney function is not impaired, then intravenous fluids can enhance renal phosphorus excretion. For more significant hyperphosphatemia or a situation such as tumor lysis or rhabdomyolysis, in which endogenous phosphorus generation is likely to continue, addition of an oral phosphorus binder prevents absorption of dietary phosphorus and can remove phosphorus from the body by binding the phosphorus normally secreted and absorbed by the gastrointestinal tract. Phosphorus binders are most effective when given with food. Binders containing aluminum hydroxide are especially efficient, but calcium carbonate is an effective alternative and may be preferred if there is a need to treat concomitant hypocalcemia. Aluminum hydroxide is not used for chronic conditions because of the risk of aluminum intoxication. Preservation of renal function, for example with alkalinization of urine in rhabdomyolysis or tumor lysis, is an important adjunct because this will permit continued excretion of phosphorus. If the hyperphosphatemia is not responding to conservative management, especially if renal insufficiency is supervening, then dialysis may be necessary to increase phosphorus removal.

Dietary phosphorus restriction is necessary for diseases causing chronic hyperphosphatemia. However, such diets are often difficult to follow given the abundance of phosphorus in a variety of foods. Dietary restriction is often sufficient in conditions such as hypoparathyroidism or mild renal insufficiency. For more problematic hyperphosphatemia, such as with moderate renal insufficiency and end-stage renal disease, phosphorus binders are usually necessary. These include calcium carbonate, calcium acetate, and sevelamer hydrochloride. Aluminum-containing phosphorus binders are no longer used in chronic renal insufficiency because of the risk of aluminum toxicity. The risk is especially high if the patient is also taking oral citrate, which increases gastrointestinal absorption of aluminum. The exclusive reliance in renal insufficiency on calcium-containing binders is diminishing as a result of concerns about systemic calcification. Dialysis directly removes phosphorus from the blood in end-stage renal disease, but it is only an adjunct to dietary restriction and phosphorus binders in that phosphorus elimination by dialysis is not efficient enough to keep up with normal dietary intake.

45.8 Acid-Base Balance

ACID-BASE PHYSIOLOGY

Introduction and Terminology.

Close regulation of pH is necessary for cellular enzymes and other metabolic processes that function

optimally at a normal pH. Chronic mild derangements in acid-base status may interfere with normal growth and development, whereas acute severe changes in pH can be fatal. Control of acid-base balance depends on the kidneys, the lungs, and intracellular and extracellular buffers.

A normal pH is 7.35–7.45. The pH is the negative log of the hydrogen ion concentration. There is an inverse relationship between the pH and the hydrogen ion concentration. When the hydrogen ion concentration decreases, the pH increases, and when the hydrogen ion concentration increases, the pH decreases. At a pH of 7.40, the hydrogen ion concentration is 40 nanomoles/L. In contrast, a normal serum sodium concentration, 140?mEq/L, is more than 1 million times higher. Maintaining a normal pH is necessary because hydrogen ions are highly reactive and are especially likely to combine with proteins, altering their function. This occurs despite the relatively low concentration of hydrogen ions.

An acid is a substance that releases ("donates") a hydrogen ion (H^+). A base is a substance that accepts a hydrogen ion. An acid (HA) can dissociate into a hydrogen ion and a conjugate base (A^-):

A strong acid is highly dissociated, so in the above reaction there is little HA. A weak acid is poorly dissociated; not all of the hydrogen ions are released from HA. A^- acts as a base when the above reaction moves to the left. These reactions are in equilibrium. When HA is added to the system, there is dissociation of some HA until the concentrations of H^+ and A^- increase enough that a new equilibrium is reached. Addition of hydrogen ions causes a decrease in A^- and an increase in HA. Addition of A^- causes a decrease in hydrogen ions and an increase in HA.

Buffers are substances that attenuate the change in pH that occurs when acids or

bases are added to the body. Given the extremely low concentration of hydrogen ions in the body at physiologic pH, without buffers a small amount of hydrogen ions could cause a dramatic decline in the pH. Buffers prevent the decrease in pH by binding the added hydrogen ions:

The increase in hydrogen ion concentration drives this reaction to the right. Similarly, when base is added to the body, buffers prevent the pH from increasing by releasing hydrogen ions:

The decrease in the hydrogen ion concentration caused by the addition of base to the body drives this reaction to the right. Buffers work by either accepting or donating hydrogen ions. A buffer functions as a base when acid is added to the body and as an acid when base is added to the body. A strong acid, such as hydrochloric acid (HCl), is an ineffective buffer because the hydrogen ion and chloride remain dissociated at all physiologic hydrogen ion concentrations; chloride never functions as a base by accepting a hydrogen ion. The best buffers are weak acids and bases. This is because a buffer works best when it is 50% dissociated (i.e., half HA and half A^-). The pH at which a buffer is 50% dissociated is the pK of a buffer. The best physiologic buffers have a pK close to 7.40. The concentration of a buffer and the pK determine a buffer's effectiveness (buffering capacity). When the pH is less than the pK of a buffer, there is more HA than A^- . At a pH greater than the pK, there is more A^- than HA.

Physiologic Buffers.

There are a variety of buffers that protect the body against major changes in pH. They are divided into the bicarbonate and non-bicarbonate buffers. The bicarbonate buffer system is routinely monitored clinically. The bicarbonate buffer system is based on the relationship between carbon dioxide (CO_2) and bicarbonate (HCO_3^-):

Carbon dioxide acts as an acid, in that, after combining with water, it releases a hydrogen ion; bicarbonate acts as its conjugate base, in that it accepts a hydrogen ion. The pK of this reaction is 6.1. The Henderson-Hasselbalch equation expresses the relationship between pH, pK, and the concentrations of an acid and its conjugate base. This relationship is valid for any buffer. The Henderson-Hasselbalch equation for bicarbonate and carbon dioxide is:

The Henderson-Hasselbalch equation for the bicarbonate buffer system has three variables: pH, [HCO_3^-], and [CO_2]. Thus, if any two of these variables is known, it is possible to calculate the third. In using the Henderson-Hasselbalch equation, it is important that carbon dioxide and bicarbonate have the same units. Carbon dioxide is reported clinically as mm?Hg and must be multiplied by its solubility constant, 0.03?mmol/L/mm?Hg, before using the Henderson-Hasselbalch equation. Mathematical manipulation of the Henderson-Hasselbalch equation produces the following relationship:

At a normal hydrogen ion concentration of 40 nanomoles (pH 7.40), the P_{co_2} , which is expressed as mm?Hg in this equation, is 40 when the bicarbonate concentration is 24?mEq/L. This equation emphasizes that hydrogen ion concentration, and hence pH, can be determined by the ratio of P_{co_2} and the bicarbonate concentration.

The bicarbonate buffer system is very effective as a result of the high concentration of bicarbonate in the body (24?mEq/L) and the fact that the bicarbonate buffer system is an open system. The remaining body buffers are in a closed system. The bicarbonate buffer system is an open system because the lungs increase carbon dioxide excretion when the blood carbon dioxide concentration increases. When acid is added to the body the following reaction occurs:

In a closed system, the CO_2 would increase. The higher CO_2 concentration would lead to an increase in the reverse reaction:

This would increase the concentration of hydrogen ions, limiting the buffering capacity of bicarbonate. However, because the lungs excrete the excess carbon dioxide, the reverse reaction does not increase; this enhances the buffering capacity of bicarbonate. The same principle holds with the addition of base because the lungs decrease carbon dioxide excretion and prevent the level of carbon dioxide from falling. The lack of change in carbon dioxide concentration dramatically increases the buffering capacity of bicarbonate.

The non-bicarbonate buffers include proteins, phosphate, and bone. Protein buffers consist of extracellular proteins, mostly albumin and intracellular proteins, including hemoglobin. Proteins are effective buffers largely due to the presence of the amino acid histidine, which has a side chain that can bind or release hydrogen ions. The pK of histidine varies slightly depending on its position in the protein molecule, but its average pK is approximately 6.5. This is close enough to a normal pH

(7.4) to make histidine an effective buffer. Hemoglobin and albumin have 34 and 16 histidine molecules, respectively.

Phosphate can bind up to three hydrogen molecules so it can exist as PO_4^{3-} , HPO_4^{2-} , $H_2PO_4^{1-}$, or H_3PO_4 . However, at a physiologic pH, most phosphate exists as either HPO_4^{2-} or $H_2PO_4^{1-}$. $H_2PO_4^{1-}$ is an acid and HPO_4^{2-} is its conjugate base:

The pK of this reaction is 6.8, making phosphate an effective buffer. The concentration of phosphate in the extracellular space is relatively low, which limits the overall buffer capacity of phosphate; it is less important than albumin. However, phosphate is at a much higher concentration in the urine, where it is an important buffer (see later text). In the intracellular space, most phosphate is covalently bound to organic molecules (e.g., ATP), but it still serves as an effective buffer.

Bone is an important buffer. Bone is basic—it is composed of compounds such as sodium bicarbonate and calcium carbonate—and thus dissolution of bone releases base. This can buffer an acid load, although at the expense of bone density if this occurs over an extended period. In contrast, bone formation, by consuming base, helps to buffer excess base.

Clinically, we measure the extracellular pH, but it is the intracellular pH that affects cell function. Measurement of the intracellular pH is unnecessary because changes in the intracellular pH parallel the changes in the extracellular pH. However, the change in the intracellular pH tends to be less than the change in the extracellular pH because of the increased buffering capacity in the intracellular space.

NORMAL ACID-BASE BALANCE

The lungs and the kidneys maintain a normal acid-base balance. Carbon dioxide generated during normal metabolism is a weak acid. The lungs prevent an increase in the partial pressure of CO_2 (P_{co_2}) in the blood by excreting the massive quantities of CO_2 that the body produces. CO_2 production varies depending on the body's metabolic needs, increasing, for example, with physical activity. The rapid pulmonary response to changes in CO_2 concentration occurs via central sensing of the P_{co_2} and a subsequent increase or decrease in ventilation to maintain a normal P_{co_2} (35–45?mm?Hg). An increase in ventilation decreases the P_{co_2} and a decrease in ventilation increases the P_{co_2}.

While the lungs excrete CO_2, the kidneys must deal with endogenous acid production. An adult normally produces about 1–2?mEq/kg/24?hr of hydrogen ions. Children normally produce 2–3?mEq/kg/24?hr of hydrogen ions. The three principal sources of hydrogen ions are dietary protein metabolism, incomplete metabolism of carbohydrates and fat, and stool losses of bicarbonate. Because metabolism of protein generates hydrogen ions, endogenous acid production varies with protein intake. The complete oxidation of carbohydrates or fats to carbon dioxide and water does not generate hydrogen ions; the lungs remove the carbon dioxide. However, incomplete metabolism of carbohydrates or fats produces hydrogen ions. For example, incomplete glucose metabolism can produce lactic acid and incomplete triglyceride metabolism can produce ketoacids such as s-hydroxybutyric acid or acetoacetic acid. There is always some baseline incomplete metabolism that contributes to endogenous acid production. This increases in pathologic conditions such as lactic acidosis or diabetic ketoacidosis. Stool loss of bicarbonate is the third major source of endogenous acid production. The stomach secretes hydrogen ions, but most of the remainder of the gastrointestinal tract secretes bicarbonate and the net effect is a loss of bicarbonate from the body. In order to secrete bicarbonate, the cells of the intestine produce hydrogen ions that are released into the bloodstream. For each bicarbonate molecule lost in the stool the body gains one hydrogen ion. This source of endogenous acid production is normally minimal, but may increase dramatically in a patient with diarrhea.

The hydrogen ions from endogenous acid production are neutralized by bicarbonate, potentially causing the bicarbonate concentration to decrease. The kidneys regenerate this bicarbonate by secreting hydrogen ions. The lungs cannot regenerate bicarbonate even though loss of carbon dioxide does lower the hydrogen ion concentration:

A decrease in carbon dioxide concentration causes the reaction to move to the right, which decreases the hydrogen ion concentration, but it also lowers the bicarbonate concentration. During a metabolic acidosis, hyperventilation can lower the carbon dioxide concentration, decrease the hydrogen ion concentration, and, thus, increase the pH. However, the underlying metabolic acidosis is still present. Similarly, the kidneys cannot correct an abnormally high carbon dioxide concentration:

An increase in the bicarbonate concentration also causes the reaction to move to the right, which increases the carbon dioxide concentration while simultaneously decreasing the hydrogen ion concentration. During a respiratory acidosis, increased renal generation of bicarbonate can decrease the hydrogen ion concentration and lower the pH, but cannot repair the respiratory acidosis. These examples emphasize the independence and interrelationship of the lungs and kidneys in regulating pH. Both the lungs and the kidneys can affect the hydrogen ion concentration and hence the pH. However, only the lungs can regulate the carbon dioxide concentration and only the kidneys can regulate the bicarbonate concentration.

Renal Mechanisms.

The kidneys regulate the serum bicarbonate concentration by modifying acid excretion in the urine. This requires a two-step process. First, the renal tubules reabsorb the bicarbonate that is filtered at the glomerulus. Second, there is tubular secretion of hydrogen ions. The urinary excretion of hydrogen ions generates bicarbonate that neutralizes endogenous acid production. The tubular actions necessary for renal acid excretion occur throughout the nephron (Fig. 45–5).

The reabsorption of filtered bicarbonate is a necessary first step in renal regulation of acid-base balance. A normal adult has a GFR of approximately 180?L/24?hr. This fluid enters Bowman's space with a bicarbonate concentration that is essentially identical to the plasma concentration, normally 24?mEq/L. Multiplying 180?L times 24?mEq/L indicates that more than 4,000?mEq of bicarbonate enter Bowman's space each day. This bicarbonate, if not reclaimed along the nephron, would be lost in the urine. Such massive loss of bicarbonate would cause a profound metabolic acidosis.

The proximal tubule reclaims about 85% of the filtered bicarbonate. The final 15% is reclaimed after the proximal tubule, mostly in the ascending limb of the loop of Henle. Figure 45–6 illustrates the mechanisms responsible for bicarbonate reabsorption in the proximal tubule. The key concept is that bicarbonate molecules are not transported from the tubular fluid into the cells of the proximal tubule. Rather, hydrogen ions are secreted into the tubular fluid, leading to conversion of filtered bicarbonate into carbon dioxide and water. The secretion of hydrogen ions by the cells of the proximal tubule is coupled to generation of intracellular bicarbonate, which is transported across the basolateral membrane of the proximal tubule cell, and enters the capillaries. The bicarbonate produced in the cell replaces the

bicarbonate filtered at the glomerulus.

Increased bicarbonate reabsorption by the cells of the proximal tubule—the result of increased hydrogen ion secretion—occurs

Figure 45.8-5 Tubular sites involved in acid-base balance. The proximal tubule is the site where most filtered bicarbonate is reclaimed, even though other sites along the nephron, especially the thick ascending limb of the loop of Henle, reabsorb some of the filtered bicarbonate. The collecting duct is the principal location for the hydrogen ion secretion that acidifies the urine. The proximal tubule generates the ammonia that serves as a urinary buffer in he collecting duct.

in a variety of clinical situations. Volume depletion increases bicarbonate reabsorption. This is partially mediated by activation of the renin-angiotensin system; angiotensin II increases bicarbonate reabsorption. Increased bicarbonate reabsorption in the proximal tubule is one of the mechanisms that accounts for the metabolic alkalosis that may occur in some patients with volume depletion. Other stimuli that increase bicarbonate reabsorption include hypokalemia and an increased P_{CO_2} . This partially explains the observations that hypokalemia causes a metabolic alkalosis and that a respiratory acidosis leads to a compensatory increase in serum bicarbonate concentration.

Stimuli that decrease bicarbonate reabsorption in the proximal tubule may cause a decrease in the serum bicarbonate concentration. A decrease in the P_{CO_2} (respiratory alkalosis) decreases proximal tubule bicarbonate reabsorption, partially mediating the decrease in the serum bicarbonate concentration that compensates for a respiratory alkalosis. Parathyroid hormone decreases proximal tubule bicarbonate reabsorption; hyperparathyroidism may cause a mild metabolic acidosis. A variety of medications and diseases cause a metabolic acidosis by impairing bicarbonate reabsorption in the proximal tubule. Examples include the medication acetazolamide, which directly inhibits carbonic anhydrase, and the many disorders that cause a proximal RTA (see Chapter 521).

After reclaiming filtered bicarbonate, the kidneys perform the second step in renal acid-base handling, the excretion of endogenous acid production. Excretion of acid occurs mostly in the collecting duct, with a small role for the distal tubule.

Along with secretion of hydrogen ions by the tubular cells lining the collecting duct, adequate excretion of endogenous acid requires the presence of urinary buffers. The hydrogen pumps in the collecting duct cannot lower the urine pH below 4.5. The hydrogen ion concentration at pH 4.5 is less than 0.04?mEq/L; it would require more than 25?L of water with a pH of 4.5 to excrete 1?mEq of hydrogen ions. A 10-kg child, with an endogenous acid production of 20?mEq of hydrogen ions each day, would need to have a daily urinary output of more than 500?L without the presence of urinary buffers. As in the blood, buffers in the urine attenuate the decrease in pH that occurs with the addition of hydrogen ions. The two principal urinary buffers are phosphate and ammonia.

Urinary phosphate is proportional to dietary intake. Whereas most of the phosphate filtered at the glomerulus is reabsorbed in the proximal tubule, the urinary phosphate concentration is usually much greater than the serum phosphate concentration. This allows phosphate to serve as an effective buffer via the following reaction:

The pK of this reaction is 6.8, making phosphate an effective buffer as the urinary pH decreases from 7.0 to 5.0 within the collecting duct. Whereas phosphate is an effective buffer, its buffering capacity is limited by its concentration; there is no mechanism for increasing urinary phosphate excretion in response to changes in acid-base status.

In contrast, ammonia production can be modified, allowing for regulation of acid excretion. The buffering capacity of ammonia is based on the reaction of ammonia with hydrogen ions to form ammonium:

The cells of the proximal tubule are the source of the excreted ammonia, mostly through metabolism of glutamine via the following reactions:

The metabolism of glutamine generates two ammonium ions. In addition, the metabolism of a-ketoglutarate generates two bicarbonate molecules. The ammonium ions are secreted into the lumen of the proximal tubule while the bicarbonate molecules exit the proximal tubule cells via the basolateral Na^+ , $3HCO_3^-$ co-transporter (see Fig. 45–6). This would seem to accomplish the goal of excreting hydrogen ions (as NH_4^+) and regenerating bicarbonate molecules. However, the ammonium

Figure 45.8-6 Reabsorption of filtered bicarbonate in the proximal tubule. The Na+,K+-ATPase (1) excretes sodium across the basolateral cell membrane, maintaining a low intracellular sodium concentration. The low intracellular sodium concentration provides the energy for the Na+,H+ antiporter (2), which exchanges sodium from the tubular lumen for intracellular hydrogen ions. The hydrogen ions that are secreted into the tubular lumen then combine with filtered bicarbonate to generate carbonic acid. Carbon dioxide and water are produced from carbonic acid (H2CO3). This reaction is catalyzed by luminal carbonic anhydrase (3). Carbon dioxide diffuses into the cell and combines with OH^- ions to generate bicarbonate. This reaction is catalyzed by an intracellular carbonic anhydrase (4). The dissociation of water generates an OH^- ion and an H+ ion. The Na+,H+ (2) antiporter secretes the hydrogen ions. Bicarbonate ions cross the basolateral membrane and enter the blood via the $3HCO3^-$ /1Na+ co-transporter (5). The energy for the $3HCO3^-$ /1Na+ co-transporter comes from the negatively charged cell interior, which makes it electrically favorable to transport a net negative charge (i.e., three bicarbonates and only one sodium) out of the cell.

ions secreted in the proximal tubule do not remain within the tubular lumen. Cells of the thick ascending limb of the loop of Henle reabsorb the ammonium ions. The end result is that there is a high medullary interstitial concentration of ammonia, but the tubular fluid entering the collecting duct does not have significant amounts of ammonium ions. Moreover, the hydrogen ions that were secreted with ammonia, as

ammonium ions, in the proximal tubule enter the bloodstream, canceling the effect of the bicarbonate generated in the proximal tubule. The excretion of ammonium ions, and hence hydrogen ions, is dependent on the cells of the collecting duct.

The cells of the collecting duct secrete hydrogen ions and regenerate bicarbonate, which is returned to the bloodstream (Fig. 45–7). This bicarbonate neutralizes endogenous acid production. Phosphate and ammonia buffer the hydrogen ions secreted by the collecting duct. Ammonia is an effective buffer because of the high concentrations in the medullary interstitium and because the cells of the collecting duct are permeable to ammonia, but not permeable to ammonium. As ammonia diffuses into lumen of the collecting duct, the low urine pH causes almost all of the ammonia to be converted into ammonium. This maintains a low luminal ammonia concentration. Because the luminal pH is lower than the pH in the medullary interstitium, there is a higher concentration of ammonia within the medullary interstitium than in the tubular lumen, favoring movement of ammonia into the tubular lumen. Even though the concentration of ammonium in the tubular lumen is higher than in the interstitium, the cells of the collecting duct are impermeable to ammonium, preventing back diffusion of ammonium out of the tubular lumen. This permits ammonia to be an effective buffer.

Figure 45.8-7 Secretion of hydrogen ions in the collecting duct. The dissociation of water generates an OH^- ion and an H^+ ion. The H^+ ATPase (1) secretes hydrogen ions into the tubular lumen. Bicarbonate is formed when OH^- ion combines with carbon dioxide in a reaction mediated by carbonic anhydrase (2). Bicarbonate ions cross the basolateral membrane and enter the blood via the $HCO3^-$/Cl^- exchanger (3). The hydrogen ions in the tubular lumen are buffered by phosphate and ammonia. Ammonia (NH_3) can diffuse from the peritubular fluid into the tubular lumen, but ammonium ($NH4^+$) cannot pass through the cells of the collecting duct.

The kidneys adjust hydrogen ion excretion based on physiologic needs. There is variation in endogenous acid production, largely due to diet, and pathophysiologic stresses, such as diarrheal losses of bicarbonate, that increase the need for acid excretion. Hydrogen excretion is increased by upregulating hydrogen ion secretion in the collecting duct. This causes the pH of the urine to decrease. This response is fairly prompt, occurring within hours of an acid load, but it is limited by the buffering capacity of the urine; the hydrogen pumps in the collecting duct cannot lower the pH to less than 4.5. A more significant increase in acid excretion requires upregulation of ammonia production by the proximal tubule so that there is more ammonia available to serve as a buffer in the tubular lumen of the collecting duct. This response to a low serum pH reaches its maximum within 5 or 6 days; ammonia excretion can increase approximately 10-fold from baseline.

Acid excretion by the collecting duct increases in a number of different clinical situations. The extracellular pH is the most important regulator of renal acid excretion. A decrease in the extracellular pH from either a respiratory or metabolic acidosis causes an increase in renal acid excretion. Aldosterone stimulates hydrogen ion excretion in the collecting duct, causing an increase in the serum bicarbonate concentration. This explains the metabolic alkalosis that occurs with primary hyperaldosteronism or secondary hyperaldosteronism due to volume depletion.

Hypokalemia increases acid secretion, both by stimulating ammonia production in the proximal tubule and increasing hydrogen ion secretion in the collecting duct. Hypokalemia therefore tends to produce a metabolic alkalosis. Hyperkalemia causes the opposite effects, which may cause a metabolic acidosis.

In patients with an increased pH, the kidney has two principal mechanisms for correcting the problem. First, less bicarbonate is reabsorbed in the proximal tubule, leading to an increase in urinary bicarbonate losses. Second, in a limited number of specialized cells, the process for secretion of hydrogen ions by the collecting duct (see Fig. 45–7) can be reversed, leading to secretion of bicarbonate into the tubular lumen and secretion of hydrogen ions into the peritubular fluid, where they enter the bloodstream.

CLINICAL ASSESSMENT OF ACID-BASE DISORDERS

The following equation, a rearrangement of the Henderson- Hasselbalch equation, emphasizes the relationship between the

P_{co_2} , the bicarbonate concentration, and the hydrogen ion concentration:

An increase in the P_{co_2} or a decrease in the bicarbonate concentration increases the hydrogen ion concentration; the pH decreases. A decrease in the P_{co_2} or an increase in the bicarbonate concentration decreases the hydrogen ion concentration; the pH increases.

Terminology.

Acidemia is a pH below normal (<7.35) and *alkalemia* is a pH above normal (>7.45). An *acidosis* is a pathologic process that causes an increase in the hydrogen ion concentration and an *alkalosis* is a pathologic process that causes a decrease in the hydrogen ion concentration. whereas acidemia is always accompanied by an acidosis, a patient can have an acidosis and a low, normal, or high pH. For example, a patient may have a mild metabolic acidosis, but a simultaneous, severe respiratory alkalosis; the net result may be alkalemia. Acidemia and alkalemia indicate the pH abnormality; acidosis and alkalosis indicate the pathologic process that is taking place.

A *simple acid-base disorder* is a single primary disturbance. During a simple metabolic disorder, there is respiratory compensation. With a metabolic acidosis, the decrease in the pH increases the ventilatory drive, causing a decrease in the P_{co_2} . The decrease in the carbon dioxide concentration leads to an increase in the pH. This *appropriate respiratory compensation* is expected with a primary metabolic acidosis. Despite the decrease in the carbon dioxide concentration, appropriate respiratory compensation is not a respiratory alkalosis, even though it is sometimes erroneously called a “compensatory respiratory alkalosis.” A low P_{co_2} can be due to a primary respiratory alkalosis or due to appropriate respiratory compensation for a metabolic acidosis. Appropriate respiratory compensation also occurs with a primary

metabolic alkalosis, although in this case the carbon dioxide concentration increases to attenuate the increase in the pH. The respiratory compensation for a metabolic process happens quickly and is complete within 12–24?hr.

During a primary respiratory process, there is metabolic compensation, mediated by the kidneys. The kidneys respond to a respiratory acidosis by increasing hydrogen ion excretion, thereby increasing bicarbonate generation and raising the serum bicarbonate concentration. The kidneys increase bicarbonate excretion to compensate for a respiratory alkalosis; the serum bicarbonate concentration decreases. Unlike appropriate respiratory compensation, it takes 3–4 days for the kidneys to complete *appropriate metabolic compensation*. There is, however, a small and rapid compensatory change in the bicarbonate concentration during a primary respiratory process. The expected appropriate metabolic compensation for a respiratory disorder is dependent on whether the process is acute or chronic.

A *mixed acid-base disorder* is present when there is more than one primary acid-base disturbance. For example, an infant with bronchopulmonary dysplasia may have a respiratory acidosis from chronic lung disease and a metabolic alkalosis from the furosemide used to treat the chronic lung disease. More dramatically, a child with pneumonia and sepsis may have severe acidemia due to a combined metabolic acidosis due to lactic acid and respiratory acidosis from ventilatory failure.

There are formulas for calculating the appropriate metabolic or respiratory compensation for the six primary simple acid-base disorders (Table 45–3). The appropriate compensation is expected in a simple disorder; it is not optional. If a patient does not have the appropriate compensation, then a mixed acid-base disorder is present. For example, a patient has a primary metabolic acidosis with a serum bicarbonate concentration of 10?mEq/L. The expected respiratory compensation is a carbon dioxide concentration of 23?mm?Hg ± 2 (1.5 × 10 + 8 ± 2 = 23 ± 2;

TABLE 45.8-3 -- **Appropriate Compensation During Simple Acid-Base Disorders**

Disorder	Expected Compensation
Metabolic acidosis	$PCO_2 = 1.5 \times [HCO_3^-] + 8 \pm 2$
Metabolic alkalosis	PCO_2 increases by 7?mm?Hg for each 10?mEq/L increase in the serum [HCO_3^-]
Respiratory acidosis	
Acute	[HCO_3^-] increases by 1 for each 10?mm?Hg increase in the PCO_2
Chronic	[HCO_3^-] increases by 3.5 for each 10?mm?Hg increase in the PCO_2
Respiratory alkalosis	
Acute	[HCO_3^-] falls by 2 for each 10?mm?Hg decrease in the PCO_2
Chronic	[HCO_3^-] falls by 4 for each 10?mm?Hg decrease in the PCO_2

see Table 45–3). If the patient's carbon dioxide concentration is more than 25?mm?Hg, then a concurrent respiratory acidosis is present; the carbon dioxide concentration is higher than expected. A patient may have a respiratory acidosis despite a carbon dioxide level below the “normal” value of 35–45?mm?Hg. In this example, a carbon dioxide concentration less than 21?mm?Hg indicates a concurrent respiratory alkalosis; the carbon dioxide concentration is lower than expected.

Diagnosis.

A systematic evaluation of an arterial blood gas, combined with the clinical history, can usually explain the patient's acid-base disturbance. Assessment of an arterial blood gas requires knowledge of normal values (Table 45–4). In most cases this is accomplished via a three-step process (Fig. 45–8):

1. Determine whether acidemia or alkalemia is present.
2. Determine a cause of the acidemia or alkalemia.
3. Determine whether a mixed disorder is present.

The first step in analyzing an acid-base disturbance is usually straightforward. The patient has either acidemia or alkalemia. Most patients with an acid-base disturbance have an abnormal pH, although there are two exceptions. The first exception is in the patient with a mixed disorder, wherein the two processes have opposite effects on the pH (e.g., a metabolic acidosis and a respiratory alkalosis) and cause comparable in magnitude, albeit opposite, changes in the hydrogen ion concentration. The second exception is in the patient with a simple chronic respiratory alkalosis; the appropriate metabolic compensation is, in some instances, enough to normalize the pH. In both of these situations of patients with a normal pH, the presence of an acid-base disturbance is deduced because of the abnormal carbon dioxide and/or bicarbonate levels. Determining the acid-base disturbance in these situations requires proceeding to the third step of this process (see later text).

The second step requires inspection of the serum bicarbonate and carbon dioxide concentrations to determine a cause of the abnormal pH (see Fig. 45–8). In most cases there is only one obvious explanation for the abnormal pH. In some mixed disorders, however, there may be two possibilities (e.g., a high P_{co_2} and a low [HCO_3^-] in a patient with acidemia). In such cases the patient has two causes of the

abnormal pH (a metabolic acidosis and a respiratory acidosis in this instance), and it is unnecessary to proceed to the third step.

TABLE 45.8-4 -- Normal Values of an Arterial Blood Gas

pH	7.35–7.45
[HCO_3^-]	20–28?mEq/L
PCO_2	35–45?mm?Hg

Figure 45.8-8 Three-step process for interpreting acid-base disturbances. In the first step, determine whether the pH is low (acidemia) or high (alkalemia). In the second step, establish an explanation for the acidemia or alkalemia. In the third step, calculate the expected compensation (see Table 45–3) and determine whether a mixed disturbance is present. Met. Alk. = Metabolic alkalosis; Met. Acid. = Metabolic acidosis; Resp. Alk. = Respiratory alkalosis; Resp. Acid. = Respiratory acidosis.

The third step requires determining whether the patient's compensation is appropriate. The patient is assumed to have the primary disorder diagnosed in the second step and the expected compensation is calculated (see Table 45–3). If the compensation is appropriate, then a simple acid-base disorder is present. If the compensation is not appropriate, then a mixed disorder is present. The identity of the second disorder is determined by deciding whether the compensation is too little or too much compared with what was expected (see Fig. 45–8).

The history is always useful in evaluating and diagnosing patients with acid-base disturbances. This is especially true with a respiratory process. The expected metabolic compensation for a respiratory process changes based on whether the process is acute or chronic. This can only be deduced by the history. For example, the metabolic compensation for a patient with an acute respiratory acidosis is less than the compensation for a chronic respiratory acidosis. In a patient with a respiratory acidosis, a small increase in the bicarbonate concentration would be consistent with a simple acute respiratory acidosis or a mixed disorder (a chronic respiratory acidosis and a metabolic acidosis). Only the history can differentiate among these possibilities. Knowledge of the length of the respiratory process and the presence or absence of a risk factor for a metabolic acidosis (e.g., diarrhea) allows the correct conclusion to be reached.

Metabolic Acidosis

Metabolic acidosis occurs frequently in hospitalized children; diarrhea is the most common etiology. For a patient with an unknown medical problem, the presence of a metabolic acidosis is often helpful diagnostically, because it suggests a relatively narrow differential diagnosis.

Patients with a metabolic acidosis have a low serum bicarbonate concentration, although not all patients with a low serum bicarbonate concentration have a metabolic acidosis. The exception is the patient with a respiratory alkalosis, which causes a decrease in the serum bicarbonate as part of appropriate renal compensation. In a patient with an isolated metabolic acidosis, there is a predictable decrease in the blood carbon dioxide concentration:

A mixed acid-base disturbance is present if the respiratory compensation is not appropriate. If the P_{CO_2} is greater than predicted, then the patient has a concurrent respiratory acidosis. A lower P_{CO_2} than predicted indicates a concurrent respiratory alkalosis or, less commonly, an isolated respiratory alkalosis. Because the appropriate respiratory compensation for a metabolic acidosis never normalizes the patient's pH, the presence of a normal pH and a low bicarbonate concentration only occurs if some degree of respiratory alkalosis is present. In this situation, distinguishing an isolated chronic respiratory alkalosis from a mixed metabolic acidosis and acute respiratory alkalosis may only be possible clinically. In contrast, the combination of a low serum pH and a low bicarbonate concentration only occurs if a metabolic acidosis is present.

Etiology and Pathophysiology.

There are many causes of a metabolic acidosis (Box 45–12), including the following three basic mechanisms:

Box 45.8-12. Causes of Metabolic Acidosis

NORMAL ANION GAP

Diarrhea

Renal tubular acidosis (RTA)

Distal (type I) (MIM * 179800/602722 †)

Proximal RTA (MIM 604278 ‡ .)

Hyperkalemic (type IV)

Urinary tract diversions

Posthypocapnia

Ammonium chloride intake

INCREASED ANION GAP

Lactic acidosis

Tissue hypoxia (hypoperfusion, hypoxemia, anemia)

Liver failure

Malignancy

Intestinal bacterial overgrowth

Inborn errors of metabolism

Medications (e.g., nucleoside analogues, metformin)

Ketoacidosis

Diabetic ketoacidosis

Starvation ketoacidosis

Alcoholic ketoacidosis

Kidney failure

Starvation ketoacidosis

Alcoholic ketoacidosis

Kidney failure

Poisoning

Ethylene glycol

Methanol

Salicylate

Inborn errors of metabolism

*MIM refers to the database number from the Mendelian Inheritance in Man (http://www3.ncbi.nlm.nih.gov/Omim/)
†Along with these genetic disorders, distal RTA may be secondary to renal disease or medications.
‡Most cases of proximal RTA are not due to this primary genetic disorder. Proximal RTA is usually part of Fanconi syndrome, which has multiple etiologies (see Chapter 521)

- Loss of bicarbonate from the body.
- Impaired ability to excrete acid by the kidney.
- Addition of acid to the body (exogenous or endogenous).

Diarrhea, the most common cause of metabolic acidosis in children, causes a loss of bicarbonate from the body. The amount of bicarbonate lost in the stool depends on the volume of diarrhea and the bicarbonate concentration of the stool, which tends to increase with more severe diarrhea. The kidneys attempt to balance the losses by increasing acid secretion, but metabolic acidosis occurs when this compensation is inadequate. Diarrhea often causes volume depletion as a result of losses of sodium and water, potentially exacerbating the acidosis by causing hypoperfusion and a lactic acidosis. In addition, diarrheal losses of potassium lead to hypokalemia. Moreover, the volume depletion causes increased production of aldosterone. This stimulates renal retention of sodium, helping to maintain intravascular volume, but also leads to increased urinary losses of potassium, exacerbating the hypokalemia.

There are three forms of *renal tubular acidosis* (RTA): distal (type I), proximal (type II), and hyperkalemic (type IV) (see Chapter 521). In distal RTA, children may have accompanying hypokalemia, hypercalciuria, nephrolithiasis, and nephrocalcinosis. Failure to thrive caused by chronic metabolic acidosis is the most common presenting complaint. There are autosomal dominant and autosomal recessive forms of distal RTA. The autosomal dominant form is relatively mild; many patients do not present until adulthood. Autosomal recessively inherited distal RTA is more severe and is often associated with deafness. Patients with distal RTA cannot acidify their urine and, thus, have a urine pH > 5.5 despite a metabolic acidosis.

Proximal RTA is rarely present in isolation. In most patients, proximal RTA is part of Fanconi syndrome, a generalized dysfunction of the proximal tubule. This leads to

glycosuria, aminoaciduria, and excessive urinary losses of phosphate and uric acid. The presence of a low serum uric acid level, glycosuria, and aminoaciduria is helpful diagnostically. Chronic hypophosphatemia ultimately leads to rickets in children. Rickets and/or failure to thrive may be the presenting complaint. The ability to acidify the urine is intact in proximal RTA; thus, untreated patients have a urine pH < 5.5. However, bicarbonate therapy increases bicarbonate losses in the urine and the urine pH increases.

In hyperkalemic RTA, renal excretion of acid and potassium is impaired. Hyperkalemic RTA is due to either an absence of aldosterone or an inability of the kidney to respond to aldosterone (see Chapter 521). In severe aldosterone deficiency, as occurs with congenital adrenal hyperplasia due to 21a-hydroxylase deficiency, the hyperkalemia and metabolic acidosis are accompanied by hyponatremia and volume depletion from renal salt wasting. Incomplete aldosterone deficiency causes less severe electrolyte disturbances; children may have isolated hyperkalemic RTA, hyperkalemia without acidosis, or isolated hyponatremia. Patients may have aldosterone deficiency due to decreased renin production by the kidney; renin normally stimulates aldosterone synthesis. Children with hyporeninemic hypoaldosteronism usually have either isolated hyperkalemia or hyperkalemic RTA. The manifestations of aldosterone resistance depend on the severity of the resistance. In the autosomal recessive form of pseudohypoaldosteronism type I, which is due to an absence of the sodium channel that normally responds to aldosterone, there is often severe salt wasting and hyponatremia. In contrast, the aldosterone resistance in kidney transplant patients usually produces either isolated hyperkalemia or hyperkalemic RTA; hyponatremia is unusual. Similarly, the medications that cause hyperkalemic RTA do not cause hyponatremia. Pseudohypoaldosteronism type II, an autosomal recessive disorder called **Gordon syndrome,** is a unique cause of hyperkalemic RTA because the genetic defect causes volume expansion and hypertension.

Children with *abnormal urinary tracts*, usually secondary to congenital malformations, may require diversion of urine through intestinal segments. Ureterosigmoidostomy, anastomosis of a ureter to the sigmoid colon, almost always produces a metabolic acidosis and hypokalemia. Consequently, ileal conduits are now the more commonly used procedure, even though there is still a risk of a metabolic acidosis.

The *appropriate metabolic compensation for a chronic respiratory alkalosis* is a decrease in renal acid excretion. The resultant decrease in the serum bicarbonate concentration lessens the alkalemia caused by the respiratory alkalosis. If the respiratory alkalosis resolves quickly, the patient continues to have a decreased serum bicarbonate concentration, causing acidemia due to a metabolic acidosis. This resolves over 1–2 days via increased acid excretion by the kidneys.

Lactic acidosis most commonly occurs when inadequate oxygen delivery to the tissues leads to anaerobic metabolism and excess production of lactic acid. Lactic acidosis may be secondary to hypoperfusion, severe anemia, or hypoxemia. When the underlying cause of the lactic acidosis is alleviated, the liver is able to metabolize the accumulated lactate into bicarbonate, correcting the metabolic acidosis. There is normally some tissue production of lactate that is metabolized by the liver. In children with severe liver dysfunction, impairment in lactate metabolism may produce a lactic acidosis. Rarely, a metabolically active malignancy grows so fast that its blood supply becomes inadequate, with resultant anaerobic metabolism and lactic acidosis. Patients who have short intestines due to small bowel resection can have bacterial overgrowth. In these patients excessive

bacterial metabolism of glucose into lactic acid can cause a lactic acidosis. Lactic acidosis occurs in a variety of inborn errors of metabolism, especially those affecting mitochondrial oxidation. Finally, medications can cause lactic acidosis. Antiretroviral nucleoside analogs that are used to treat HIV infection inhibit mitochondrial replication; lactic acidosis is a rare complication, although elevated serum lactate without acidosis is quite common. Metformin, commonly used for treating type 2 diabetes mellitus, is most likely to cause a lactic acidosis in patients with renal insufficiency.

In *insulin-dependent diabetes mellitus*, inadequate insulin leads to hyperglycemia and diabetic ketoacidosis (see Chapter 583). Production of acetoacetic acid and s-hydroxybutyric acid causes the metabolic acidosis. Administration of insulin corrects the underlying metabolic problem and permits conversion of acetoacetate and s-hydroxybutyrate into bicarbonate, which helps to correct the metabolic acidosis. However, in some patients, urinary losses of acetoacetate and s-hydroxybutyrate may be substantial, preventing rapid regeneration of bicarbonate. In these patients, full correction of the metabolic acidosis requires renal regeneration of bicarbonate, a slower process. The characteristic odor of the breath in diabetic ketoacidosis is from the conversion of some acetoacetic acid into acetone, a volatile ketone that leaves the blood via the lungs. The hyperglycemia causes an osmotic diuresis, usually producing volume depletion, along with substantial losses of potassium, sodium, and phosphate. Despite severe total body potassium depletion, the serum potassium level is initially often normal as a result of a shift of potassium from the intracellular space into the extracellular space because of the lack of insulin and the metabolic acidosis. Hypokalemia develops with insulin therapy unless the patient receives adequate potassium.

In *starvation ketoacidosis*, the lack of glucose leads to ketoacid production. This can produce a metabolic acidosis, although it is usually mild as a result of increased acid secretion by the kidney. In alcoholic ketoacidosis, which is much less common in children than adults, the acidosis usually follows a combination of an alcoholic binge with vomiting and poor intake of food. The acidosis is potentially more severe than with isolated starvation and the blood glucose level may be low, normal, or high.

Renal failure causes a metabolic acidosis because of the need for the kidneys to excrete the acid produced by normal metabolism. With mild or moderate renal insufficiency, the remaining nephrons are usually able to compensate by increasing acid excretion. When the GFR is less than 20–30% of normal, the compensation is inadequate and a metabolic acidosis develops. In some children, especially those with chronic renal failure due to tubular damage, the acidosis develops at a higher GFR because of a concurrent defect in acid secretion by the distal tubule (a distal RTA).

A variety of *toxic ingestions* cause a metabolic acidosis. Salicylate intoxication is

much less common since aspirin is no longer recommended for fever control in children. Acute salicylate intoxication occurs after a large overdose. Chronic salicylate intoxication is possible with gradual buildup of the drug. Especially in adults, respiratory alkalosis may be the dominant acid-base disturbance. In children, the metabolic acidosis is usually the more significant finding. Other symptoms of salicylate intoxication include fever, seizures, lethargy, and coma. Hyperventilation may be particularly marked. Tinnitus, vertigo, and hearing impairment are more likely with chronic salicylate intoxication.

Ethylene glycol, a component of antifreeze, is converted in the liver to glyoxylic and oxalic acids, causing a severe metabolic acidosis. Excessive oxalate excretion causes calcium oxalate crystals to appear in the urine, and calcium oxalate precipitation in the kidney tubules can cause renal failure. The toxicity of methanol ingestion is also dependent on liver metabolism; formic acid is the toxic end product that causes the metabolic acidosis and other sequelae, which include damage to the optic nerve and central nervous system. Symptoms may include nausea, emesis, visual impairment, and altered mental status.

Many *inborn errors of metabolism* cause a metabolic acidosis (see Chapters 74 and 75). The metabolic acidosis may be due to excessive production of ketoacids, lactic acid, and/or other organic anions. Some patients have accompanying hyperammonemia. In most patients, the acidosis only occurs episodically during acute decompensations, which may be precipitated by ingestion of specific dietary substrates, the stress of a mild illness, or poor compliance with dietary or medical therapy. In a few inborn errors of metabolism, patients have a chronic metabolic acidosis.

Clinical Manifestations.

The underlying disorder usually produces most of the signs and symptoms in children with a mild or moderate metabolic acidosis. The clinical manifestations of the acidosis are related to the degree of acidemia; patients with appropriate respiratory compensation and less severe acidemia have fewer manifestations than those with a concomitant respiratory acidosis. At a serum pH less than 7.20, there is impaired cardiac contractility and an increased risk of arrhythmias, especially if underlying heart disease or other predisposing electrolyte disorders are present. With acidemia there is a decrease in the cardiovascular response to catecholamines, potentially exacerbating hypotension in children with volume depletion or shock. Acidemia causes vasoconstriction of the pulmonary vasculature, which is especially problematic in newborn infants with persistent pulmonary hypertension (see Chapter 90.7).

The normal respiratory response to metabolic acidosis—compensatory hyperventilation—may be subtle with mild metabolic acidosis, but causes discernible increased respiratory effort with worsening acidemia. The acute metabolic effects of acidemia include insulin resistance, increased protein degradation, and reduced ATP synthesis. Chronic metabolic acidosis causes failure to thrive in children. Acidemia causes potassium to move from the intracellular space to the extracellular space, thereby increasing the serum potassium concentration. This effect is greater with a nonorganic acidosis than with an organic acidosis (e.g., lactic acidosis or ketoacidosis) or a respiratory acidosis. Severe acidemia impairs brain metabolism, eventually resulting in lethargy and coma.

Diagnosis.

The etiology of a metabolic acidosis is often apparent from the history and physical examination. Acutely, diarrhea and hypoperfusion are common causes of a metabolic acidosis. Hypoperfusion, which causes a lactic acidosis, is usually apparent on physical examination and can be secondary to dehydration, acute blood loss, shock, or heart disease. Failure to thrive suggests a chronic metabolic acidosis, as happens with renal insufficiency or RTA. New onset of polyuria occurs in children with undiagnosed diabetes mellitus and diabetic ketoacidosis. Metabolic acidosis with seizures and/or a depressed sensorium, especially in an infant, warrants consideration of an inborn error of metabolism. However, meningitis and sepsis with lactic acidosis are a more common explanation for metabolic acidosis with neurologic signs and symptoms. Identification of toxic ingestions, such as ethylene glycol or methanol, is especially important because of the potential excellent response to specific therapy. A variety of medications cause a metabolic acidosis; they may be prescribed or accidentally ingested. Hepatomegaly and metabolic acidosis may occur in children with sepsis, congenital or acquired heart disease, hepatic failure, or inborn errors of metabolism.

Basic laboratory tests in a child with a metabolic acidosis should include BUN, creatinine, serum glucose, urinalysis, and electrolytes. An elevated BUN and creatinine are present in renal insufficiency, whereas an elevated BUN/creatinine ratio (>20:1) supports a diagnosis of prerenal azotemia and the

possibility of hypoperfusion with lactic acidosis. Metabolic acidosis, hyperglycemia, glycosuria, and ketonuria support a diagnosis of diabetic ketoacidosis. Less commonly, this combination is secondary to an inborn error of metabolism. Starvation causes ketosis, but the metabolic acidosis, if present, is mild ($HCO_3^- > 18$). A moderate or severe metabolic acidosis with ketosis cannot be explained by starvation. Most children with ketosis due to poor intake and metabolic acidosis have a concomitant disorder such as gastroenteritis with diarrhea as an explanation for the metabolic acidosis. Alternatively, the combination of metabolic acidosis with ketosis occurs in inborn errors of metabolism; these patients may have hyperglycemia, normoglycemia, or hypoglycemia. Adrenal insufficiency may cause metabolic acidosis and hypoglycemia. Metabolic acidosis with hypoglycemia occurs with liver failure. Metabolic acidosis, normoglycemia, and glycosuria occur in children when type II RTA is part of the Fanconi syndrome; the defect in reabsorption of glucose by the proximal tubule of the kidney causes the glycosuria.

The serum potassium level is often abnormal in children with a metabolic acidosis. Even though a metabolic acidosis causes potassium to move from the intracellular space to the extracellular space, many patients with a metabolic acidosis have a low serum potassium level due to excessive body losses of potassium. With diarrhea, there are high stool losses of potassium and often secondary renal losses of potassium, whereas in type I or type II RTA there are increased urinary losses of potassium. In diabetic ketoacidosis, urinary losses of potassium are high, but the

shift of potassium out of cells due to lack of insulin and metabolic acidosis is especially significant. Consequently, the initial serum potassium can be low, normal, or high, even though total body potassium is almost always decreased. The serum potassium is usually increased in patients with acidosis due to renal insufficiency; urinary potassium excretion is impaired. The combination of metabolic acidosis, hyperkalemia, and hyponatremia occurs in patients with severe aldosterone deficiency or aldosterone resistance. Patients with less severe type IV RTA often have only hyperkalemia and metabolic acidosis. Very ill children with metabolic acidosis may have an elevated serum potassium level as a result of a combination of renal insufficiency, tissue breakdown, and shift of potassium from the intracellular space to the extracellular space secondary to the metabolic acidosis.

The *plasma anion gap* is useful for evaluating patients with a metabolic acidosis. It divides patients into two diagnostic groups: normal anion gap or increased anion gap. The following formula determines the anion gap:

A normal anion gap is 8–16. Figure 45–9 illustrates the basis for the anion gap. The number of serum anions must equal the number of serum cations in order to maintain electrical neutrality. The anion gap is the difference between the measured cation

Figure 45.8-9 The anion gap. The anion gap is the difference between the sodium concentration and the combined concentrations of chloride and bicarbonate (*vertical line*). In both a gap and non-gap metabolic acidosis, there is a decrease in the bicarbonate concentration. There is an increase in unmeasured anions (UA) in patients with a gap metabolic acidosis. In a non-gap metabolic acidosis, there is an increase in the serum chloride concentration. UC = unmeasured cations.

(sodium) and the measured anions (chloride + bicarbonate). The anion gap is also the difference between the unmeasured cations (e.g., potassium, magnesium, calcium) and the unmeasured anions (e.g., albumin, phosphate, urate, sulfate). An increased anion gap occurs when there is an increase in unmeasured anions. For example, with a lactic acidosis there is endogenous production of lactic acid, which is composed of positively charged hydrogen ions and negatively charged lactate anions. The hydrogen ions are largely buffered by serum bicarbonate, resulting in a decrease in the bicarbonate concentration. The hydrogen ions that are not buffered by bicarbonate cause the serum pH to decrease. The lactate anions remain, and this causes the increase in the anion gap.

An increase in unmeasured anions, along with hydrogen ion generation, is present in all causes of an increased gap metabolic acidosis (see Box 45–12). In diabetic ketoacidosis, the ketoacids s-hydroxybutyrate and acetoacetate are the unmeasured anions. In renal failure, there is retention of unmeasured anions, including phosphate, urate, and sulfate. However, the increase in unmeasured anions in renal failure is usually less than the decrease in the bicarbonate concentration. Renal failure is thus a mix of an increased gap and normal gap metabolic acidosis. The normal gap metabolic acidosis is especially prominent in children with renal failure due to tubular damage, as occurs with renal dysplasia or obstructive uropathy, because these patients actually have a concurrent RTA. The unmeasured anions in toxic ingestions vary: formate in methanol intoxication, glycolate in ethylene glycol intoxication, and lactate and ketoacids in salicylate intoxication. In inborn errors of metabolism, the unmeasured anions depend on the specific etiology and may include ketoacids, lactate, and/or other organic anions. In a few inborn errors of metabolism, the acidosis occurs without generation of unmeasured anions and, thus, the anion gap is normal.

A normal anion gap metabolic acidosis occurs when there is a decrease in the bicarbonate concentration without an increase in the unmeasured anions. For example, with diarrhea there is a loss of bicarbonate in the stool, causing a decrease in the serum pH and bicarbonate concentration. As shown in Figure 45–9 , the serum chloride concentration increases in order to maintain electrical neutrality. Hyperchloremic metabolic acidosis is an alternative term for a normal anion gap metabolic acidosis. However, calculation of the anion gap is more precise than using the chloride concentration to differentiate a normal and increased gap metabolic acidosis in that the anion gap directly determines the presence of unmeasured anions. In contrast, electrical neutrality dictates that the chloride concentration increases or decreases depending on the serum sodium concentration, making the chloride concentration a less reliable predictor of unmeasured anions than the more direct measure, the anion gap.

Approximately 11?mEq of the anion gap is normally secondary to albumin. A decrease in the albumin concentration of 1?g/dL decreases the anion gap by roughly 4?mEq/L. Similarly, albeit less commonly, an increase in unmeasured cations, such as calcium, potassium, or magnesium, decreases the anion gap. Conversely, a decrease in unmeasured cations is a very unusual cause of an increased anion gap. Because of these variables, the broad range of a normal anion gap and other variables, the presence of a normal or increased anion gap is not always reliable in differentiating the causes of a metabolic acidosis, especially when the metabolic acidosis is mild. Moreover, some patients have more than one explanation for their metabolic acidosis, such as the child with diarrhea and lactic acidosis due to hypoperfusion. The anion gap should not be interpreted in dogmatic isolation; consideration of other laboratory abnormalities and the clinical history improves its diagnostic utility.

Treatment.

The most effective therapeutic approach for patients with a metabolic acidosis is repair of the underlying disorder, if possible. For example, the administration of insulin in diabetic ketoacidosis and restoration of adequate perfusion in lactic acidosis eventually result in normalization of acid-base balance. In other diseases, the use of bicarbonate therapy is clearly indicated because the underlying disorder is irreparable. Children with metabolic acidosis due to RTA or chronic renal failure require long-term base therapy. Patients with acute renal failure and metabolic acidosis need base therapy until their kidney's ability to excrete hydrogen normalizes. In other disorders, the cause of the metabolic acidosis eventually resolves, but base therapy is necessary during the acute illness. In salicylate poisoning, for example, alkali administration increases renal clearance of salicylate and decreases the amount of salicylate in brain cells. Short-term base therapy is often necessary in other poisonings (e.g., ethylene glycol or methanol) and inborn errors of metabolism (e.g., pyruvate carboxylase deficiency or propionic acidemia).

Some inborn errors of metabolism require chronic base therapy.

The use of base therapy in diabetic ketoacidosis and lactic acidosis is controversial, with little evidence that it improves patient outcome and a variety of potential side effects. The risks of giving sodium bicarbonate include the possibility of causing hypernatremia or volume overload. Furthermore, the patient may have overcorrection of the metabolic acidosis once the underlying disorder resolves because metabolism of lactate or ketoacids generates bicarbonate. The rapid change from acidemia to alkalemia can cause a variety of problems, including hypokalemia and hypophosphatemia. Bicarbonate therapy increases the generation of carbon dioxide, which can accumulate in patients with respiratory failure. Because carbon dioxide readily diffuses into cells, the administration of bicarbonate can lower the intracellular pH, potentially worsening cell function. Despite the potential complications, base therapy is often given to children with severe lactic acidosis and diabetic ketoacidosis.

Oral base therapy is given to children with chronic metabolic acidosis. Sodium bicarbonate tablets are available for older children. Younger children generally take citrate solutions; the liver generates bicarbonate from citrate. Citrate solutions are available as sodium citrate, potassium citrate, and a 1:1 mix of sodium and potassium citrate. The patient's potassium needs usually dictate the choice. Children with type I or type II RTA may have hypokalemia and benefit from potassium supplements, whereas most children with chronic renal failure cannot tolerate additional potassium.

Oral or intravenous base can be used in acute metabolic acidosis; intravenous therapy is generally used when a rapid response is necessary. Sodium bicarbonate may be given as a bolus, usually at a dose of 1?mEq/kg, in an emergency situation. A more gentle approach is to add sodium bicarbonate or sodium acetate to the patient's intravenous fluids, remembering to remove an equal amount of sodium chloride from the solution to avoid giving an excessive sodium load. Careful monitoring is mandatory so that the dose of base can be appropriately titrated. An alternative to sodium bicarbonate is the intravenous agent Carbicarb, which corrects metabolic acidosis with less generation of carbon dioxide, an advantage in patients with respiratory insufficiency. However, Carbicarb has not been shown to be superior to sodium bicarbonate, and it has some of the same potential side effects. Hemodialysis is another option for correcting a metabolic acidosis, and it is an appropriate choice in patients with renal insufficiency, especially if significant uremia or hyperkalemia is also present. Hemodialysis is advantageous for correcting the metabolic acidosis due to methanol or ethylene glycol intoxication because hemodialysis removes the offending toxin. In addition, these patients often have a severe metabolic acidosis that does not respond easily to intravenous

bicarbonate therapy. Peritoneal dialysis is another option for correcting the metabolic acidosis due to renal insufficiency, although, because it relies on lactate as the source of base, it may not correct the metabolic acidosis in patients with concomitant renal failure and lactic acidosis.

Many causes of metabolic acidosis require specific therapy. Administration of a glucocorticoid and a mineralocorticoid is necessary in patients with adrenal insufficiency. Patients with diabetic ketoacidosis require insulin therapy, whereas patients with lactic acidosis respond to measures that alleviate tissue hypoxia. Along with correction of acidosis, patients with methanol or ethylene glycol should receive an agent that prevents the breakdown of these agents to their toxic metabolites. Traditionally this has been done with an ethanol infusion, but fomepizole is now an effective alternative with fewer side effects. Both agents work by inhibiting alcohol dehydrogenase, the enzyme that performs the first step in the metabolism of ethylene glycol or methanol. There are a variety of disease-specific therapies for patients with a metabolic acidosis due to an inborn error of metabolism.

Metabolic Alkalosis

Metabolic alkalosis in children is most commonly secondary to emesis or diuretic use. The serum bicarbonate concentration is increased with a metabolic alkalosis, even though a respiratory acidosis also leads to a compensatory elevation of the serum bicarbonate concentration. With a simple metabolic alkalosis, however, the pH is elevated; alkalemia is present. Patients with a respiratory acidosis are acidemic. A metabolic alkalosis, by decreasing ventilation, causes appropriate respiratory compensation. PCO_2 increases by 7?mm?Hg for each 10?mEq/L increase in the serum bicarbonate concentration. Appropriate respiratory compensation never exceeds a PCO_2 of 55–60?mm?Hg. The patient has a concurrent respiratory alkalosis if the PCO_2 is less than the expected compensation. A greater than expected PCO_2 occurs with a concurrent respiratory acidosis.

Etiology and Pathophysiology.

The kidneys normally respond promptly to a metabolic alkalosis by increasing base excretion. Two processes are therefore usually present to produce a metabolic alkalosis. The first process is the generation of the metabolic alkalosis. This requires addition of base to the body. The second process is the maintenance of the metabolic alkalosis. This requires impairment in the kidney's ability to excrete base.

The etiologies of a metabolic alkalosis are divided into two categories based on the urinary chloride (Box 45–13). The alkalosis in patients with a low urinary chloride is maintained by *volume depletion*, and, thus, volume repletion is necessary for correction of the alkalosis. The volume depletion in these patients is due to losses of sodium and potassium, but the loss of chloride is usually greater than that of sodium and potassium combined. Because chloride losses are the dominant cause of the volume depletion, these patients require chloride to correct their volume depletion and their metabolic alkalosis; they are called “chloride responsive.” In contrast, the patients with an elevated urinary chloride do not respond to volume repletion; they are called “chloride resistant.”

Emesis or nasogastric suction results in *loss of gastric fluid*, which has a high content of HCl. Generation of hydrogen ions by the gastric mucosa causes simultaneous release of bicarbonate into the bloodstream. Normally the hydrogen ions in gastric fluid are reclaimed in the small intestine (by neutralizing secreted

bicarbonate). Thus, there is no net loss of acid. With loss of gastric fluid, this does not occur and the patient develops a metabolic alkalosis. This is the generation phase of the metabolic alkalosis.

The maintenance phase of the metabolic alkalosis from gastric losses is due to the volume depletion (“chloride depletion” from gastric loss of HCl). Volume depletion interferes with urinary loss of bicarbonate, the normal renal response to a metabolic alkalosis. During volume depletion, a variety of mechanisms prevent renal bicarbonate loss. First, there is a reduction in the GFR so less bicarbonate is filtered. Second, volume depletion increases reabsorption of sodium and bicarbonate in the proximal tubule, limiting the amount of bicarbonate that can be excreted in the urine. This effect is mediated by angiotensin II and adrenergic stimulation of the kidney, which are both increased in response to volume depletion. Third, the increase in aldosterone during volume depletion increases bicarbonate reabsorption and hydrogen ion secretion in the collecting duct.

In addition to volume depletion, gastric losses are usually associated with hypokalemia as a result of both gastric loss of potassium and, most importantly, increased urinary potassium losses. The increased urinary losses of potassium are mediated by aldosterone, due to volume depletion, and the increase in intracellular potassium secondary to the metabolic alkalosis, which causes potassium to move into the cells of the kidney, causing increased potassium excretion. Hypokalemia contributes to the maintenance of the metabolic alkalosis by decreasing bicarbonate loss. More specifically, hypokalemia increases hydrogen ion secretion in the distal nephron and stimulates ammonia production in the proximal tubule. Ammonia production enhances renal excretion of hydrogen ions.

Many of the effects that maintain the metabolic alkalosis in patients with gastric losses and secondary volume depletion maintain and generate the metabolic alkalosis in the other diseases with chloride responsive metabolic alkalosis. Patients receiving *loop or thiazide diuretics* can develop a metabolic alkalosis. Diuretic use leads to volume depletion, which increases angiotensin II, aldosterone, and adrenergic stimulation of the kidney. Diuretics increase delivery of sodium to the distal nephron, further enhancing acid excretion. Moreover, diuretics cause hypokalemia, which increases acid excretion by the kidney. The increase in renal acid excretion generates the metabolic

Box 45.8-13. Causes of Metabolic Alkalosis

CHLORIDE RESPONSIVE (urinary chloride <15?mEq/L)

- Gastric losses (emesis or nasogastric suction)
- Diuretics (loop or thiazide)
- Chloride losing diarrhea (MIM 214700)
- Chloride-deficient formula
- Cystic fibrosis (MIM 219700)
- Post hypercapnia

CHLORIDE RESISTANT (urinary chloride >20?mEq/L)

- High blood pressure (BP)
  - Adrenal adenoma or hyperplasia
  - Glucocorticoid-remedial aldosteronism (MIM 103900)
  - Renovascular disease
  - Renin-secreting tumor
  - 17a-hydroxylase deficiency (MIM 202110)
  - 11ß-hydroxylase deficiency (MIM 202010)
  - Cushing syndrome
  - 11ß-hydroxysteroid dehydrogenase deficiency (MIM 218030)

alkalosis and the decrease in bicarbonate loss maintains the metabolic alkalosis. In addition, patients on diuretics have a “contraction alkalosis.” Diuretic use causes fluid loss without bicarbonate, and thus the remaining body bicarbonate is contained in a smaller total body fluid compartment. The bicarbonate concentration increases, helping to generate the metabolic alkalosis.

Diuretics are often used in patients with edema, such as in patients with nephrotic syndrome, heart failure, or liver failure. In many of these patients, metabolic alkalosis resulting from diuretic use develops despite the continued presence of edema. This is because the effective intravascular volume is low, and it is the effective intravascular volume that stimulates the compensatory mechanisms that cause and maintain a metabolic alkalosis. Many of these patients have a decreased effective intravascular volume before beginning diuretic therapy, increasing the likelihood of diuretic-induced metabolic alkalosis.

Diuretic use increases chloride excretion in the urine. Consequently, while a patient is receiving diuretics, the urine chloride is typically high (>20?mEq/L). After the diuretic effect has worn off, the urinary chloride is low (<15?mEq/L) due to appropriate renal chloride retention in response to volume depletion. Thus, categorization of diuretics based on urinary chloride depends on the timing of the measurement. However, the metabolic alkalosis from diuretics is clearly chloride responsive; it only corrects after adequate volume repletion. This is the rationale for including it among the chloride-responsive causes of a metabolic alkalosis.

Most patients with diarrhea develop a metabolic acidosis due to stool losses of bicarbonate. In *chloride-losing diarrhea*, an autosomal recessive disorder, there is a defect in the normal intestinal exchange of bicarbonate for chloride, causing excessive stool losses of chloride (see Chapter 320.12). In addition, stool losses of hydrogen ions and potassium cause metabolic alkalosis and hypokalemia, both of which are exacerbated by increased renal hydrogen and potassium losses due to volume depletion. Treatment is with oral supplements of potassium and sodium chloride. Use of a gastric proton-pump inhibitor, by decreasing gastric HCl production, reduces the volume of diarrhea and decreases the need for electrolyte supplementation.

An *infant formula with an extremely low chloride content* has led to chloride deficiency and volume depletion. The infants fed this formula, which is no longer available, developed a metabolic alkalosis and hypokalemia. *Cystic fibrosis* can cause metabolic alkalosis, hypokalemia, and hyponatremia due to excessive losses of sodium chloride in sweat (see Chapter 393). The volume depletion causes the metabolic alkalosis and hypokalemia through increased urinary losses while the hyponatremia, a less common finding, is secondary to sodium loss combined with renal water conservation in an effort to protect the intravascular volume (“appropriate” ADH production).

A *post-hypercapnic metabolic alkalosis* occurs after the correction of a chronic respiratory acidosis. This is typically seen in patients with chronic lung disease who are placed on a ventilator. During chronic respiratory acidosis, appropriate renal compensation leads to an increase in the serum bicarbonate concentration. This elevated bicarbonate concentration, since it is still present after the acute correction of the respiratory acidosis, causes a metabolic alkalosis. The metabolic alkalosis persists because the patient with a chronic respiratory alkalosis is intravascularly depleted due to chloride loss that occurred during the initial metabolic compensation for the primary respiratory acidosis. In addition, many children with a chronic respiratory acidosis receive diuretics, further decreasing the intravascular volume. The metabolic alkalosis responds to correction of the intravascular volume deficit.

The chloride-resistant causes of metabolic alkalosis can be subdivided based on blood pressure. The *patients with hypertension* have either increased aldosterone or act like they have increased aldosterone. Aldosterone levels are elevated in children with adrenal adenomas or hyperplasia. Aldosterone causes renal retention of sodium, with resultant hypertension. Metabolic alkalosis and hypokalemia result from aldosterone- mediated renal excretion of hydrogen ions and potassium. Urinary chloride is not low in that these patients are volume overloaded, not volume depleted. The volume expansion and hypertension allow normal excretion of sodium and chloride despite the presence of aldosterone. This is known as the “mineralocorticoid escape phenomenon.”

In glucocorticoid-remedial aldosteronism, an autosomal dominant disorder, there is excess production of aldosterone due to the presence of an aldosterone synthase gene that is regulated by ACTH (see Chapter 572). Glucocorticoids effectively treat this disorder by inhibiting ACTH production by the pituitary, downregulating the inappropriate aldosterone production. Renovascular disease and renin-secreting tumors both cause excessive renin, leading to an increase in aldosterone, although hypokalemia and metabolic alkalosis are less common findings than hypertension. In two forms of congenital adrenal hyperplasia, 11s-hydroxylase deficiency and 17a-hydroxylase deficiency, there is excessive production of the mineralocorticoid 11-deoxycorticosterone (see Chapter 570). Hypertension, hypokalemia, and metabolic alkalosis are more likely in 17a-hydroxylase deficiency than in 11s-hydroxylase deficiency. These patients respond to glucocorticoids because the excess production of 11-deoxycorticosterone is under the control of ACTH.

Cushing syndrome frequently causes hypertension. Cortisol has some mineralocorticoid activity and high levels can produce hypokalemia and metabolic

alkalosis in patients with Cushing syndrome.

Cortisol can bind to the mineralocorticoid receptors in the kidney and function as a mineralocorticoid. This normally does not occur because 11s-hydroxysteroid dehydrogenase in the kidney converts cortisol to cortisone, which does not bind to the mineralocorticoid receptor. In 11s-hydroxysteroid dehydrogenase deficiency, cortisol is not converted in the kidney to cortisone. Cortisol is therefore available to bind to the mineralocorticoid receptor in the kidney and act like a mineralocorticoid. These patients, despite low levels of aldosterone, are hypertensive and hypokalemic, and they have a metabolic alkalosis. The same phenomenon can occur with excessive intake of natural licorice because a component of natural licorice, glycyrrhizic acid, inhibits 11s-hydroxysteroid dehydrogenase. The autosomal dominant disorder **Liddle syndrome** is secondary to an activating mutation of the sodium channel in the distal nephron. Upregulation of this sodium channel is one of the principal actions of aldosterone. Because this sodium channel is continuously open, these children have the features of hyperaldosteronism, including hypertension, hypokalemia, and metabolic alkalosis, but low serum levels of aldosterone.

Bartter syndrome and Gitelman syndrome are autosomal recessive disorders with *normal blood pressure*, elevated urinary chloride, metabolic alkalosis, and hypokalemia (see Chapter 523). In Bartter syndrome, patients have a defect in sodium and chloride reabsorption in the loop of Henle. This leads to excessive urinary losses of sodium and chloride, and, like patients on loop diuretics, there is volume depletion and secondary hyperaldosteronism, causing hypokalemia and metabolic alkalosis. Gitelman syndrome is usually milder than Bartter syndrome. Patients have renal sodium and chloride wasting with volume depletion due to an absence of the thiazide-sensitive sodium-chloride transporter in the distal tubule. Like patients on a thiazide diuretic they develop volume depletion and secondary

hyperaldosteronism with hypokalemia and metabolic alkalosis. Children with Gitelman syndrome have hypocalciuria and hypomagnesemia.

Excessive base intake can cause a metabolic alkalosis. These patients do not have a low urine chloride, unless there is associated volume depletion. In the absence of volume depletion, excess base is rapidly corrected via renal excretion of bicarbonate. Rarely, massive base intake can cause a metabolic alkalosis by overwhelming the kidney's ability to excrete bicarbonate. This may occur in infants given baking soda as a “home remedy” for colic or stomach upset. Each teaspoon of baking soda has 42?mEq of sodium bicarbonate. Infants have increased vulnerability due to a lower GFR, limiting the rate of compensatory renal bicarbonate excretion. A metabolic alkalosis may also occur in patients who receive a large amount of sodium bicarbonate during cardiopulmonary resuscitation. Blood products are anticoagulated with citrate, which is converted into bicarbonate by the liver. Patients who receive large amounts of blood products may develop a metabolic alkalosis. Iatrogenic metabolic alkalosis can occur as a result of acetate in total parenteral nutrition. Aggressive use of bicarbonate therapy in a child with a lactic acidosis or diabetic ketoacidosis may cause a metabolic alkalosis. This is especially likely in a patient in whom the underlying cause of the lactic acidosis is successfully corrected (e.g., restoration of intravascular volume in a patient with severe dehydration). Once the cause of the lactic acidosis resolves, lactate can be converted by the liver into bicarbonate, and, when combined with infused bicarbonate, this can create a metabolic alkalosis. A similar phenomenon can occur in a child with diabetic ketoacidosis because the administration of insulin allows ketoacids to be metabolized, producing bicarbonate. However, this rarely occurs because of judicious use of bicarbonate therapy in diabetic ketoacidosis and because there are usually significant pretreatment losses of ketoacids in the urine, preventing massive regeneration of bicarbonate. Base administration is most likely to cause a metabolic alkalosis in patients who have an impaired ability to excrete bicarbonate in the urine. This occurs in patients with concurrent volume depletion or renal insufficiency.

Clinical Manifestations.

The symptoms in patients with a metabolic alkalosis are often related to the underlying disease and associated electrolyte disturbances. Children with the chloride-responsive causes of metabolic alkalosis often have symptoms related to volume depletion, such as thirst and lethargy. In contrast, children with chloride unresponsive causes may have symptoms related to hypertension.

Alkalemia causes potassium to shift into the intracellular space, causing a decrease in the extracellular potassium concentration. Moreover, alkalemia leads to increased urinary losses of potassium. Finally, increased potassium losses are present in many of the conditions that cause a metabolic alkalosis. Therefore, most patients with a metabolic alkalosis have hypokalemia, and symptoms may be related to the hypokalemia (see Chapter 45.4).

The symptoms of a metabolic alkalosis are due to the associated alkalemia. The magnitude of the alkalemia is related to the severity of the metabolic alkalosis and the presence of concurrent respiratory acid-base disturbances. During alkalemia, the ionized calcium concentration decreases as a result of increased binding of calcium to albumin. The decrease in the ionized calcium concentration may cause symptoms of tetany (e.g., carpopedal spasm) and seizures.

Arrhythmias are a potential complication of a metabolic alkalosis, and this risk increases if there is concomitant hypokalemia. Alkalemia increases the risk of digoxin toxicity, and antiarrhythmic medications are less effective in the presence of alkalemia. In addition, alkalemia may decrease cardiac output. A metabolic alkalosis causes a compensatory increase in the PCO_2 by decreasing ventilation. In patients with underlying lung disease, the decrease in ventilatory drive can cause hypoxia. The hypoventilation in patients with severe metabolic alkalosis can cause hypoxia in patients with normal lungs.

Diagnosis.

Measurement of the urinary chloride concentration is the most helpful test in differentiating among the causes of a metabolic alkalosis. The urine chloride is low in patients with a metabolic alkalosis resulting from volume depletion, unless there is a defect in renal handling of chloride. Urine chloride is superior to urine sodium in assessing volume status in patients with a metabolic alkalosis because the normal

renal response to a metabolic alkalosis is to excrete bicarbonate. Because bicarbonate is negatively charged, it can only be excreted with a cation, usually sodium and potassium. Hence, a patient with a metabolic alkalosis excretes sodium in the urine despite the presence of volume depletion, which normally causes avid sodium retention. Urine sodium cannot be used to assess volume status in the presence of a metabolic alkalosis; urine chloride, in the absence of a defect in renal chloride handling, is a good indicator of volume status and differentiates among the chloride-resistant and chloride-responsive causes of a metabolic alkalosis.

Diuretics and gastric losses are the most common causes of metabolic alkalosis and are usually readily apparent from the patient history. Occasionally, metabolic alkalosis, usually with hypokalemia, may be a clue to the presence of bulimia or surreptitious diuretic use (see Chapter 104). Patients with bulimia have a low urine chloride, indicating that they have volume depletion as a result of an extrarenal etiology, but there is no alternative explanation for their volume depletion. Surreptitious diuretic use may be diagnosed by obtaining a urine toxicology screen for diuretics. The urine chloride is increased while diuretics are being used but is low when the patient stops taking diuretics. Rarely, children with mild Bartter syndrome or Gitelman syndrome are misdiagnosed as having bulimia or abusing diuretics. The urine chloride is always elevated in Bartter syndrome and Gitelman syndrome and the urine toxicology screen for diuretics is negative. Metabolic alkalosis and hypokalemia is occasionally the initial manifestation of cystic fibrosis. An elevated sweat chloride finding is diagnostic.

Patients with a metabolic alkalosis and a high urinary chloride are separated based on blood pressure. Children with a normal blood pressure may have Bartter syndrome or Gitelman syndrome. Excess base administration is another diagnostic possibility, but this is usually apparent from the history. In patients with sodium bicarbonate ingestion (e.g., baking soda), which may be unreported by the parent, the metabolic alkalosis usually occurs with significant hypernatremia. In addition, unless volume depletion is superimposed, the metabolic alkalosis from base ingestion self-resolves once the source of base is eliminated.

Measuring serum concentrations of renin and aldosterone differentiates children with a metabolic alkalosis, a high urinary chloride level, and elevated blood pressure. Both renin and aldosterone are elevated in children with either renovascular disease or a renin-secreting tumor. Aldosterone is high and renin is low in patients with adrenal adenomas or hyperplasia and glucocorticoid-remediable aldosteronism. Renin and aldosterone are low in children with Cushing syndrome, Liddle syndrome, licorice ingestion, 17a-hydroxylase deficiency, 11s-hydroxylase deficiency, and 11s-hydroxysteroid dehydrogenase deficiency. An elevated 24-hr urine cortisol level is diagnostic of Cushing syndrome, which is suspected by the presence of the other classic features of this disease (see Chapter 571). 11-Deoxycorticosterone levels are elevated in 17a-hydroxylase deficiency and 11s-hydroxylase deficiency.

Treatment.

The approach to therapy of metabolic alkalosis depends on the severity of the alkalosis and the underlying etiology. In children with a mild metabolic alkalosis ($[HCO_3^-] < 32$)

intervention is often unnecessary, although this depends on the specific circumstances. In a child with congenital heart disease receiving a stable dose of a loop diuretic, a mild alkalosis does not require treatment. In contrast, intervention may be appropriate in a child with a worsening mild metabolic alkalosis due to nasogastric suction. The presence of a concurrent respiratory acid-base disturbance also influences therapeutic decision-making. A patient with a concurrent respiratory acidosis should have some increase in bicarbonate due to metabolic compensation, and thus the severity of the pH elevation is more important than the bicarbonate concentration. In contrast, a patient with a respiratory alkalosis and a metabolic alkalosis is at risk for severe alkalemia; treatment may be indicated, even if the increase in bicarbonate is only mild.

Intervention is usually necessary in children with moderate or severe metabolic alkalosis. The most effective approach is always to address the underlying etiology. In some children, nasogastric suction may be decreased or discontinued. Alternatively, the addition of a gastric proton pump inhibitor reduces gastric secretion and losses of HCl. Diuretics are an important cause of metabolic alkalosis and, if tolerated, they should be eliminated or the dose reduced. Adequate potassium supplementation or the addition of a potassium-sparing diuretic is also helpful in a child with a metabolic alkalosis caused by diuretics. Potassium-sparing diuretics not only decrease renal potassium losses, but, by blocking the action of aldosterone, they decrease hydrogen ion secretion in the distal nephron, increasing urinary bicarbonate excretion. Many children cannot tolerate discontinuation of diuretic therapy, thus potassium supplementation and potassium-sparing diuretics are the principal therapeutic approach. Occasionally, in cases of severe metabolic alkalosis, acetazolamide is an option. Acetazolamide, a carbonic anhydrase inhibitor, decreases reabsorption of bicarbonate in the proximal tubule, causing significant bicarbonate loss in the urine. The patient must be monitored closely because acetazolamide produces major losses of potassium in the urine and increases fluid losses, potentially necessitating a reduction in other diuretics.

Most children with a metabolic alkalosis have one of the chloride-responsive etiologies. In these situations, administration of sufficient sodium chloride and potassium chloride to correct the volume deficit and the potassium deficit is necessary to correct the metabolic alkalosis. This may not be an option in the child who has volume depletion due to diuretics because volume repletion may be contraindicated. Adequate replacement of gastric losses of sodium and potassium in a child with nasogastric tube can minimize or prevent the development of the metabolic alkalosis. With adequate intravascular volume and a normal serum potassium concentration, the kidney is able to excrete the excess bicarbonate within a couple of days.

In children with the chloride resistant causes of a metabolic alkalosis that are associated with hypertension, volume repletion is contraindicated because it exacerbates the hypertension and does not repair the metabolic alkalosis. Ideally, treatment focuses on eliminating the excess aldosterone effect. Adrenal adenomas can be resected, licorice intake can be eliminated, and renovascular disease can be repaired. Glucocorticoid-remediable aldosteronism, 17a-hydroxylase deficiency, and 11s-hydroxylase deficiency respond to administration of glucocorticoids. The

mineralocorticoid effect of cortisol in 11s-hydroxysteroid dehydrogenase deficiency can be decreased by using spironolactone, which blocks the mineralocorticoid receptor. In contrast, children with Liddle syndrome do not respond to spironolactone; however, either triamterene or amiloride is effective therapy because they block the sodium channel that is constitutively active in Liddle syndrome.

In children with Bartter syndrome and Gitelman syndrome, therapy includes oral potassium supplementation and potassium- sparing diuretics. Children with Gitelman syndrome often require magnesium supplementation, whereas children with severe Bartter syndrome often benefit from indomethacin.

Respiratory Acidosis

A respiratory acidosis is an inappropriate increase in the blood carbon dioxide (P_{CO_2}). Carbon dioxide is a byproduct of metabolism, and it is removed from the body by the lungs. During a respiratory acidosis, there is a decrease in the effectiveness of carbon dioxide removal by lungs. A respiratory acidosis is secondary to either pulmonary diseases, such as severe bronchiolitis, or nonpulmonary disease, such as a narcotic overdose. Even though body production of carbon dioxide can vary, normal lungs are able to accommodate this variation; excess production of carbon dioxide is never an isolated cause of a respiratory acidosis. With impaired alveolar ventilation, the rate of body production of carbon dioxide may affect the severity of the respiratory acidosis, but this is usually not a significant factor.

A respiratory acidosis causes a decrease in the blood pH, but there is normally a metabolic response that partially compensates, minimizing the severity of the acidemia. The acute metabolic response to a respiratory alkalosis occurs within minutes. The metabolic compensation for an acute respiratory acidosis is secondary to titration of acid by non-bicarbonate buffers. This buffering of hydrogen ions causes a predictable increase in the serum bicarbonate concentration: Plasma bicarbonate increases by 1 for each 10?mm?Hg increase in the P_{CO_2} (acute compensation).

With a chronic respiratory acidosis there is more significant metabolic compensation and, thus, less severe acidemia than an acute respiratory acidosis with the same increase in P_{CO_2} . During a chronic respiratory acidosis, the kidneys increase acid excretion. This response occurs over 3–4 days and causes a predictable increase in the serum bicarbonate concentration: Plasma bicarbonate increases by 3.5 for each 10?mm?Hg increase in the Pco_2 (chronic compensation).

The increase of serum bicarbonate during a chronic respiratory acidosis is associated with a decrease in body chloride. After acute correction of a chronic respiratory acidosis, the plasma bicarbonate continues to be increased, and the patient has a metabolic alkalosis. Because of the chloride deficit, this is a chloride responsive metabolic alkalosis; it corrects once the patient's chloride deficit is replaced.

A mixed disorder is present if the metabolic compensation is inappropriate. A higher than expected bicarbonate occurs in the setting of a concurrent metabolic alkalosis and a lower than expected bicarbonate occurs in the setting of a concurrent metabolic acidosis. Evaluating whether compensation is appropriate during a respiratory acidosis requires clinical knowledge of the acuity of the process, because the expected compensation is different depending on whether the process is acute or chronic.

The P_{CO_2} cannot be interpreted in isolation to determine whether a patient has a respiratory acidosis. A respiratory acidosis is always present if a patient has acidemia and an elevated P_{CO_2} . However, an elevated P_{CO_2} also occurs as appropriate respiratory compensation for a simple metabolic alkalosis. The patient is alkalemic; this is not a respiratory acidosis. During a mixed disturbance a patient can have a respiratory acidosis and a normal or even a low P_{CO_2} . This may occur in a patient with a metabolic acidosis; a respiratory acidosis is present if the patient does not have appropriate respiratory compensation (i.e., the P_{CO_2} is higher than expected based on the severity of the metabolic acidosis).

Etiology and Pathophysiology.

The causes of a respiratory acidosis are either pulmonary or non-pulmonary (Box 45–14). Central nervous system disorders can decrease the activity of the central

respiratory center, reducing ventilatory drive. In addition, a variety of medications and illicit drugs suppress the respiratory center. The signals from the respiratory center need to be transmitted to the respiratory muscles via the nervous system. Respiratory muscle failure can be secondary to disruption of the signal from the central nervous system in the spinal cord, the phrenic nerve, or the neuromuscular junction. Disorders directly affecting the muscles of respiration can prevent adequate ventilation, causing a respiratory acidosis.

Mild or moderate lung disease often causes a respiratory alkalosis as a result of hyperventilation secondary to hypoxia or stimulation of lung mechanoreceptors or chemoreceptors. Only more severe lung disease causes a respiratory acidosis. Upper airway diseases, by impairing air entry into the lungs, may decrease ventilation, producing a respiratory acidosis.

Increased production of carbon dioxide is never the sole cause of a respiratory acidosis, but can increase the severity of the disease in a patient with decreased ventilation of carbon dioxide. Increased production of carbon dioxide occurs in patients with fevers, hyperthyroidism, excess caloric intake, and high levels of physical activity. Increased respiratory muscle work also increases carbon dioxide production.

Clinical Manifestations.

Patients with a respiratory acidosis are often tachypneic in an effort to correct the inadequate ventilation. Exceptions include patients with a respiratory acidosis resulting from central nervous system depression and patients who are on the verge of complete respiratory failure secondary to fatigue of the respiratory muscles.

The symptoms of respiratory acidosis are related to the severity of the hypercarbia. Acute respiratory acidosis is usually more symptomatic than chronic respiratory acidosis. Symptoms are also increased by concurrent hypoxia or metabolic acidosis. In a patient breathing room air, hypoxia is always present if a respiratory acidosis is present. The potential central nervous system manifestations of respiratory acidosis include anxiety, dizziness, headache, confusion, asterixis, myoclonic jerks, hallucinations, psychosis, coma, and seizures.

Acidemia, no matter the etiology, affects the cardiovascular system. An arterial pH less than 7.20 impairs cardiac contractility and the normal response to catecholamines, both in the heart and the peripheral vasculature. Hypercapnia causes vasodilation, most dramatically in the cerebral vasculature, but hypercapnia produces vasoconstriction of the pulmonary circulation. Respiratory acidosis increases the risk of cardiac arrhythmias, especially in a child with underlying cardiac disease.

Diagnosis.

The history and physical often point to a clear etiology. For the obtunded patient with poor respiratory effort, evaluation of the central nervous system is often indicated. This may include imaging studies (e.g., CT or MRI) and potentially a lumbar puncture. A toxicology screen for illicit drugs may also be appropriate. A response to naloxone is both diagnostic and therapeutic. In many of the diseases affecting the respiratory muscles, there is evidence of weakness in other muscles. Stridor is a clue that the child may have upper airway disease. Along with a physical examination, a chest radiograph is often helpful in diagnosing pulmonary disease.

In many patients, respiratory acidosis may be multifactorial. For example, a child with bronchopulmonary dysplasia, an intrinsic lung disease, may worsen due to respiratory muscle dysfunction from severe hypokalemia due to chronic diuretic therapy. Conversely, a child with muscular dystrophy, a muscle disease, may worsen because of an aspiration pneumonia.

For a patient with respiratory acidosis, calculation of the gradient between the alveolar oxygen concentration and the arterial oxygen concentration, the A-a gradient, is useful for distinguishing between poor respiratory effort and intrinsic lung disease. The A-a gradient is increased if the hypoxemia is due to intrinsic lung disease (see Chapters 356 and 357).

Treatment.

Respiratory acidosis is best managed by treating the underlying etiology. In some instances, the response is very

rapid, such as after the administration of naloxone to a patient with a narcotic overdose. In contrast, the child with pneumonia may require a number of days of antibiotic therapy before the respiratory status improves. In many children with a chronic respiratory acidosis, there is no curative therapy, although an acute respiratory illness superimposed on a chronic respiratory condition is usually reversible.

All patients with an acute respiratory acidosis are hypoxic and therefore need to receive supplemental oxygen. Mechanical ventilation is necessary in some children with a respiratory acidosis. Children with a significant respiratory acidosis due to a central nervous system disease usually require mechanical ventilation because these disorders are unlikely to respond quickly to therapy. In addition, hypercarbia causes cerebral vasodilation, and the increase in intracranial pressure can be dangerous in a child with an underlying central nervous system disease. Readily reversible central nervous system depression, such as from a narcotic overdose, may not require mechanical ventilation. Decisions on mechanical ventilation for other patients depend on a number of factors. Patients with severe hypercarbia—P_{CO_2} greater than 75—usually require mechanical ventilation (see Chapters 57.3 , 57.4 , and 359). The threshold for intubation is lower if there is concomitant metabolic acidosis, a slowly responsive underlying disease, hypoxia that responds poorly to oxygen, or if the patient appears to be tiring and respiratory arrest seems likely.

In patients with a chronic respiratory acidosis, the respiratory drive is often less responsive to hypercarbia and more responsive to hypoxia. Hence, with chronic respiratory acidosis, excessive use of oxygen can blunt the respiratory drive and, therefore, increase the P_{CO_2} . In these patients, oxygen must be used cautiously.

When possible, it is best to avoid mechanical ventilation in a patient with a chronic respiratory acidosis because extubation is often difficult. However, an acute illness may necessitate mechanical ventilation in a child with a chronic respiratory acidosis. When intubation is necessary, the P_{CO_2} should only be lowered to the patient's normal baseline, which should be done gradually. These patients normally have an elevated serum bicarbonate level as a result of metabolic compensation for their respiratory acidosis. A rapid lowering of the P_{CO_2} can cause a severe metabolic alkalosis, potentially leading to complications, including cardiac arrhythmias, decreased cardiac output, and decreased cerebral blood flow. In addition, prolonged mechanical ventilation at a normal P_{CO_2} causes the metabolic compensation to resolve. When the patient is subsequently extubated, the patient will no longer benefit from metabolic compensation, causing a more severe acidemia due to the respiratory acidosis.

Respiratory Alkalosis

A respiratory alkalosis is an inappropriate reduction in the blood carbon dioxide concentration. This is usually secondary to hyperventilation, initially causing removal of carbon dioxide to surpass production. Eventually, a new steady state is achieved, with removal equaling production, albeit at a lower carbon dioxide tension (P_{CO_2}). A respiratory alkalosis not due to hyperventilation may occur in children receiving extracorporeal membrane oxygenation (ECMO) or hemodialysis, with carbon dioxide lost directly from the blood in the extracorporeal circuit.

With a simple respiratory alkalosis, the pH increases, but there is a normal metabolic response that attenuates some of the change in the blood pH. A metabolic response to an acute respiratory alkalosis occurs within minutes, mediated by hydrogen ion release from non-bicarbonate buffers. The metabolic response to an acute respiratory alkalosis is predictable: Plasma bicarbonate falls by 2 for each 10?mm?Hg decrease in the P_{CO_2} (acute compensation).

A chronic respiratory alkalosis leads to more significant metabolic compensation due to the actions of the kidneys, which decrease acid secretion, producing a decrease in the serum bicarbonate concentration. Both the proximal tubule and distal tubule decrease acid secretion. Metabolic compensation for a respiratory alkalosis develops gradually and takes 2–3 days to produce the full effect: Plasma bicarbonate falls by 4 for each 10?mm?Hg decrease in the P_{CO_2} (chronic compensation).

A chronic respiratory alkalosis is the only acid-base disturbance wherein appropriate compensation may normalize the pH, albeit above 7.40.

A mixed disorder is present if the metabolic compensation is inappropriate. A higher than expected bicarbonate occurs in the setting of a concurrent metabolic alkalosis and a lower than expected bicarbonate occurs in the setting of a concurrent metabolic acidosis. Evaluating whether compensation is appropriate during a respiratory alkalosis requires clinical knowledge of the acuity of the process, because the expected compensation is different depending on whether the process is acute or chronic.

A low P_{CO_2} does not always indicate a respiratory alkalosis. The P_{CO_2} also decreases as part of the appropriate respiratory compensation for a metabolic acidosis; this is not a respiratory alkalosis. A metabolic acidosis is the dominant acid-base disturbance in a patient with acidemia and a low P_{CO_2} , even though there could still be a concurrent respiratory alkalosis. In contrast, a respiratory alkalosis is always present in a patient with alkalemia and a low P_{CO_2} . Even a normal PCO_2 may be consistent with a respiratory alkalosis in a patient with a metabolic alkalosis because an elevated P_{CO_2} is expected as part of appropriate respiratory compensation for the metabolic alkalosis.

Etiology and Pathophysiology.

A variety of stimuli can increase the ventilatory drive and cause a respiratory alkalosis (Box 45–15). Arterial hypoxemia or tissue hypoxia stimulates peripheral chemoreceptors to signal the central respiratory center in the medulla to increase ventilation. The resultant increased respiratory effort increases the oxygen content of the blood, but depresses the P_{CO_2} . The effect of hypoxemia on ventilation begins when the oxygen saturation decreases to about 90% (P_{O_2} = 60?mm?Hg), and the hyperventilation increases as hypoxemia worsens. Acute hypoxia is a more potent stimulus for hyperventilation than chronic hypoxia and thus chronic hypoxia, as occurs in cyanotic heart disease, causes a much less severe respiratory alkalosis than an equivalent degree of acute hypoxia. There are many causes of hypoxemia or

tissue hypoxia, including primary lung disease, severe anemia, and carbon monoxide poisoning.

The lungs contain chemoreceptors and mechanoreceptors that respond to irritants and stretching, and send signals to the respiratory center to increase ventilation. For example, aspiration or pneumonia may stimulate the chemoreceptors while pulmonary edema may stimulate the mechanoreceptors. Most of the diseases that activate these receptors may also cause hypoxemia and can, therefore, potentially lead to hyperventilation via two mechanisms. Whereas patients with primary lung disease may initially have a respiratory alkalosis, worsening of the disease, combined with respiratory muscle fatigue, often causes respiratory failure and the development of a respiratory acidosis.

Hyperventilation in the absence of lung disease occurs with direct stimulation of the central respiratory center. This occurs with central nervous system diseases such as meningitis, hemorrhage, and trauma. Central hyperventilation due to lesions, such as infarcts or tumors near the central respiratory center in the midbrain, increases the rate and depth of the respiratory effort. This respiratory pattern portends a poor prognosis because these midbrain lesions are frequently fatal. Systemic processes may cause centrally mediated hyperventilation.

Although the exact mechanisms are not clear, liver disease causes a respiratory alkalosis that is usually proportional to the degree of liver failure. Pregnancy causes a chronic respiratory alkalosis, probably mediated by progesterone acting on the respiratory centers. Salicylates, although often causing a concurrent metabolic acidosis, directly stimulate the respiratory center to produce a respiratory alkalosis. The respiratory alkalosis during sepsis is probably due to cytokine release.

Hyperventilation may be secondary to an underlying disease that causes pain, stress, or anxiety. In psychogenic hyperventilation, there is no disease process accounting for the hyperventilation. This may occur in a child who has had an emotionally stressful experience. Alternatively, it may be part of a panic disorder, especially if there are repeated episodes of hyperventilation. In these patients, the symptoms of acute alkalemia increase anxiety, potentially perpetuating the hyperventilation.

A respiratory alkalosis is quite common in children receiving mechanical ventilation because the respiratory center is not controlling ventilation. In addition, these children may have a decreased metabolic rate and hence less carbon dioxide production because of sedation and paralytic medications. Normally, decreased carbon dioxide production and resultant hypocapnia decreases ventilation, but this physiologic response cannot occur in a child who cannot reduce his ventilatory effort.

Clinical Manifestations.

The disease process that is causing the respiratory alkalosis is usually more concerning than the clinical manifestations of the respiratory alkalosis. Chronic respiratory alkalosis is usually asymptomatic since metabolic compensation decreases the magnitude of the alkalemia.

Acute respiratory alkalosis may cause chest tightness, palpitations, lightheadedness, circumoral numbness, and paresthesias of the extremities. Less common manifestations include tetany, seizures, muscle cramps, and syncope. The lightheadedness and syncope are probably due to the reduction in cerebral blood flow that is caused by hypocapnia. The reduction in cerebral blood flow is the rationale for using hyperventilation to treat children with increased intracranial pressure. The paresthesias, tetany, and seizures may be partially related to the reduction in ionized calcium that occurs because alkalemia causes more calcium to bind to albumin. A respiratory alkalosis also causes a mild reduction in the serum potassium level. Patients with psychogenic hyperventilation tend to be most symptomatic from their respiratory alkalosis, and these symptoms, along with a sensation of breathlessness, exacerbate the hyperventilation.

Diagnosis.

In many patients, the hyperventilation producing a respiratory alkalosis is not clinically detectable, even with careful observation of the patient's respiratory effort. Metabolic compensation for a respiratory alkalosis causes a low serum bicarbonate concentration. When the hyperventilation is not appreciated and only serum electrolytes are evaluated, there is often a presumptive diagnosis of a metabolic acidosis. If a respiratory alkalosis is suspected, only a blood gas determination can make the diagnosis.

Hyperventilation does not always indicate a primary respiratory disorder. In some patients, the hyperventilation is appropriate respiratory compensation for a metabolic

acidosis. With a primary metabolic acidosis, acidemia is present and the serum bicarbonate is usually quite low if there is clinically detectable hyperventilation. In contrast, the serum bicarbonate never goes below 17?mEq/L as part of the metabolic compensation for acute respiratory alkalosis and simple acute respiratory alkalosis causes alkalemia.

The etiology of a respiratory alkalosis is often apparent from the physical examination or history, such as lung disease, neurologic disease, or cyanotic heart disease. Hypoxemia is a common cause of hyperventilation, and it is important to diagnose because it suggests a significant underlying disease that requires expeditious treatment. Hypoxemia may be detected on physical examination (cyanosis) or by pulse oximetry. However, normal pulse oximetry does not completely eliminate hypoxemia as the etiology of the hyperventilation. There are two reasons why pulse oximetry is not adequate for eliminating hypoxemia as a cause of a respiratory alkalosis. First, pulse oximetry is not very sensitive at detecting a mildly low pO_2 . Second, the hyperventilation during a respiratory alkalosis causes the pO_2 to increase, possibly increasing the pO_2 to a level that is not identified as abnormal by pulse oximetry. Only an arterial blood gas can completely eliminate hypoxia as an explanation for a respiratory alkalosis. Along with hypoxemia, it is important to consider processes that cause tissue hypoxia without necessarily causing hypoxemia. Examples include carbon monoxide poisoning, severe anemia, and congestive heart failure.

Lung disease without hypoxemia may cause hyperventilation. Although often apparent by history or physical examination, a chest radiograph may detect more subtle disease. Patients with a pulmonary embolism may have benign chest x-ray findings, normal pO_2 , and isolated respiratory alkalosis, even though hypoxia may eventually occur. Diagnosis of a pulmonary embolism requires a high index of suspicion and should be considered in children without another explanation for respiratory alkalosis, especially if risk factors are present, such as prolonged bed rest or a hypercoagulable state (e.g., nephrotic syndrome or lupus anticoagulant).

Treatment.

There is seldom a need for specific therapy of respiratory alkalosis. Rather, treatment focuses on the underlying disease. Mechanical ventilator settings are adjusted to correct

iatrogenic respiratory alkalosis, unless the hyperventilation has a therapeutic purpose (e.g., treatment of increased intracranial pressure).

For patients with hyperventilation secondary to anxiety, efforts should be undertaken to reassure the child, usually enlisting the parents. Along with reassurance, patients with psychogenic hyperventilation may benefit from benzodiazepines. During an acute episode of psychogenic hyperventilation, rebreathing into a paper bag increases the patient's P_{CO_2} . Using a paper bag, instead of a plastic bag, allows adequate oxygenation, but permits the carbon dioxide concentration in the bag to increase. The resultant increase in the patient's P_{CO_2} decreases the symptoms of the respiratory alkalosis that tend to perpetuate the hyperventilation. Rebreathing should only be done once other causes of hyperventilation have been eliminated; pulse oximetry during the rebreathing is prudent.

Chapter 46 - Maintenance and Replacement Therapy

Maintenance intravenous fluids are used in a child who cannot be fed enterally. Along with maintenance fluids, children may require concurrent *replacement fluids* if they have excessive losses such as may occur with drainage from a nasogastric (NG) tube or high urine output due to nephrogenic diabetes insipidus. In addition, if dehydration is present, the patient needs to receive *deficit* therapy. A child awaiting surgery may only need maintenance fluids, whereas a child with diarrheal dehydration needs maintenance and deficit therapy and may also require replacement fluids if the diarrhea continues. This chapter reviews the principles of maintenance therapy and replacement fluids. Chapter 47 discusses dehydration and the administration of deficit therapy.

Maintenance Therapy.

Children normally have large variations in their daily intake of water and electrolytes. The only exceptions are patients who receive fixed dietary regimens orally, via gastric tube, or as intravenous total parenteral nutrition. Healthy children can tolerate significant variations in intake because of the many homeostatic mechanisms that can adjust absorption and excretion of water and electrolytes (see Chapter 45). The calculated water and electrolyte needs that form the basis of maintenance therapy are not absolute requirements. Rather, these calculations provide reasonable guidelines for intravenous therapy. Children do not need to be placed on intravenous fluids simply because their intake is being monitored in a hospital and they are not taking “maintenance fluids” orally, unless there is a pathologic process present that necessitates high fluid intake (e.g., sickle cell crisis).

Maintenance fluids are most commonly necessary in preoperative and postoperative surgical patients. But, many nonsurgical patients also require maintenance fluids. It is important to recognize when it is necessary to begin maintenance fluids. A normal teenager who is given nothing by mouth (NPO) overnight for a morning procedure does not require maintenance fluids because a healthy, older patient can easily tolerate 12 or 18 hours without oral intake. In contrast, a 6-mo-old waiting for a tetralogy of Fallot repair should begin receiving intravenous fluids within 4–6?hr of his last feeding. Infants become dehydrated faster than older patients. This is especially important in a patient with tetralogy of Fallot because even mild dehydration may precipitate a cyanotic spell. More dramatically, a child with obligatory high urine output from nephrogenic diabetes insipidus should begin receiving intravenous fluids soon after being made NPO.

Maintenance fluids are generally composed of a solution of water, glucose, sodium, and potassium. This solution has the advantages of simplicity, long shelf life, low cost, and compatibility with peripheral intravenous administration. Such a solution accomplishes the major objectives of maintenance fluids (Box 46–1). Patients lose water, sodium, and potassium in their urine and stool; water is also lost from the skin and lungs. Maintenance fluids replace these losses and therefore avoid the development of dehydration and deficiencies of sodium or potassium.

The glucose in maintenance fluids provides approximately 20% of the normal caloric needs of the patient. This is enough to prevent the development of starvation ketoacidosis and diminishes the protein degradation that would occur if the patient received no calories.

The goals of maintenance fluid therapy are relatively modest. Maintenance fluids do not provide adequate calories, protein, fat, minerals, or vitamins. This is typically not problematic for a patient receiving intravenous fluids for a few days. But, it is important to remember that a patient on maintenance intravenous fluids is receiving inadequate calories and will actually lose 0.5–1% of weight each day. Thus, it is imperative that patients not remain on maintenance therapy indefinitely; total parental nutrition should be used for children who cannot be fed enterally for more than a few days. This is especially important in a patient with underlying malnutrition.

Prototypical maintenance fluid therapy does not provide electrolytes such as calcium, phosphorous, magnesium, or bicarbonate. For most patients, this is not problematic for a few days. Nevertheless, there are patients who will not tolerate this omission, usually because of excessive losses. For example a child with renal tubular acidosis wastes bicarbonate in urine. Such a patient will rapidly become acidemic unless bicarbonate is added to the maintenance fluids. It is important to remember the limitations of maintenance fluid therapy.

Box 46-1. Goals of Maintenance Fluids

Prevent dehydration

Prevent electrolyte disorders

Prevent ketoacidosis

Prevent protein degradation

Maintenance Water.

Water is a crucial component of maintenance fluid therapy. This is because of the obligatory water losses that occur during the day. These losses are both measurable

(urine and stool) and not measurable (insensible losses from the skin and lungs). Failure to replace these losses leads to having a thirsty, uncomfortable child and, ultimately, a dehydrated child.

The goal of maintenance water is to provide enough water to replace these obligatory losses. Urinary losses are approximately 60% of the total. However, the normal kidney has the ability to markedly modify water losses, with daily urine volume potentially varying by more than a factor of 20. Maintenance water is designed to provide enough water so that the kidney does not need to significantly dilute or concentrate the urine. This also provides a nice cushion so that normal homeostatic mechanisms can adjust urinary water losses to keep the patient euvolemic. This adaptability obviates the need for absolute precision in determining water requirements. This is important given the absence of absolute accuracy in the formulas for calculation of water needs. Table 46–1 provides a system for calculating maintenance water based on the patient's weight. This system emphasizes the high water needs of smaller patients. This approach is quite reliable, although calculations based on weight do overestimate the water needs of overweight patients. It is also important to remember that there is an upper limit of 2–2.5?L/24?hr in adult-sized patients. Intravenous fluids are written as an hourly rate. It is therefore often helpful to use the formulas in Box 46–2 to quickly calculate the rate of maintenance fluids.

Maintenance Electrolytes.

Sodium, potassium, and chloride are given in maintenance fluids to replace losses from urine and stool. Whereas most patients can adjust their rate of loss, maintenance electrolytes are designed not to stress the body's homeostatic mechanisms and to minimize the development of electrolyte imbalances. Maintenance requirements for sodium and potassium are shown in Box 46–3 . Adequate chloride is provided as long as at least half of the sodium and potassium are given as chloride salts.

Glucose.

Maintenance fluids usually contain 5% dextrose (D5), which provides 17 calories per 100?mL and close to 20% of the daily caloric needs. This is enough to prevent ketone production and helps minimize protein degradation. It is a diet, and a child will lose weight on this regimen. This is the principal reason why a patient needs to be started on total parental nutrition after a few days of maintenance fluids if enteral feedings are still not possible. Maintenance fluids are also lacking in such crucial nutrients as protein, fat, vitamins, and minerals.

Intravenous Solutions.

In designing fluid management, it is important to know the components of the commonly available solutions (Table 46–2). Normal saline (NS) and Ringer lactate are isotonic solutions; they have approximately the same tonicity as plasma. Isotonic fluids are generally used for the acute correction

Box 46-2. Maintenance Water Rate

0–10?kg: 4?mL/kg/hr

10–20?kg: 40?mL/hr + 2?mL/kg/hr × (wt-10?kg)

>20?kg: 60?mL/hr + 1?mL/kg/hr × (wt-20?kg)*

Body Weight	Fluid per Day
0–10?kg	100?mL/kg
11–20?kg	1,000?mL + 50?mL/kg for each kg > 10?kg
> 20?kg	1,500?mL + 20?mL/kg for each kg > 10?kg*

* *The maximum total fluid per day is normally 2,400?mL.*

of intravascular volume depletion (see Chapter 47). Half NS and 1/4 NS are the usual choices for maintenance fluid therapy in children. These solutions are available with 5% dextrose. In addition, these solutions are available with 20?mEq/L of potassium chloride, 10?mEq/L of potassium chloride, or no potassium. These are the commercially available solutions. A hospital pharmacy can prepare custom-made solutions with different concentrations of glucose, sodium, or potassium. In addition, other electrolytes such as calcium, magnesium, phosphate, acetate, and bicarbonate can be added to intravenous solutions. Custom-made solutions take time to prepare and are much more expensive than commercial solutions. The use of custom made solutions is only necessary for patients who have underlying disorders that cause

significant electrolyte imbalances. The use of premade solution saves both time and expense.

A normal plasma osmolality is 285–295?mOsm/kg. Infusing an intravenous solution peripherally with a much lower osmolality can cause water to move into red blood cells, causing hemolysis. Thus, intravenous fluids are generally designed to have an osmolality that is either close to 285 or greater (moderately higher osmolality fluids do not cause problems). Thus, ¼ NS (osmolality = 77) should not be administered peripherally, but D5 ¼ NS (osmolality = 355) or D5 ½ NS + 20?mEq/L KCl (osmolality = 472) can be administered.

Selection of Maintenance Fluids.

After calculation of water needs and electrolyte needs, children typically receive either D5 ¼ NS + 20?mEq/L?KCl or D5 ½ NS + 20?mEq/L?KCl. Children weighing less than about 20–25?kg do best with the solution containing 1/4 NS because of their high water needs per kilogram. In contrast, larger children and adults may receive the solution with ½ NS. These guidelines assume that there is no disease process present that would require an adjustment in either the volume or electrolyte composition of maintenance fluids (e.g., children with renal insufficiency may not tolerate 20?mEq/L of potassium). These solutions work well in children who have normal homeostatic mechanisms for adjusting urinary excretion of water, sodium, and potassium. In children with complicated pathophysiologic derangements, it may be necessary to empirically adjust the electrolyte composition and rate of maintenance fluids based on electrolyte measurements and assessment of fluid balance.

Variations in Maintenance Water.

The calculation of maintenance water is based on standard assumptions regarding water losses. There are patients, however, for whom these assumptions are incorrect. In order to identify such situations, it is helpful to understand the source and magnitude of normal water losses. Box 46–4 lists the three sources of normal water loss: the components

TABLE 46-2 -- Composition of Intravenous Solutions

Fluid	$[Na^+]$	$[Cl^-]$	$[K^+]$	$[Ca^{2+}]$	$[Lactate^-]$
Normal saline (0.9% NaCl)	154	154			
½ Normal saline (0.45% NaCl)	77	77			
¼ Normal saline (0.225% NaCl)	38.5	38.5			
Ringer lactate	130	109	4	3	28

Box 46-4. Components of Maintenance Water

Urine: 60%

Insensible losses: 35% (skin and lungs)

Stool: 5%

of maintenance water. Urine is the most important contributor to normal water loss. Insensible losses represent approximately one third of total maintenance water. Insensible losses are composed of evaporative losses from the skin and the lungs. These losses cannot be quantitated. The evaporative losses from the skin do not include sweat, which should be considered an additional source of water loss. Stool normally represents a minor source of water loss.

Maintenance water needs may be increased or decreased, depending on the clinical situation. This may be obvious in the case of the infant with profuse diarrhea or subtle in the case of the patient who has decreased insensible losses while in a mist tent. It is helpful to consider the sources of normal water loss and determine whether any of these sources is being modified in a specific patient. It is then necessary to adjust maintenance water and electrolyte calculations.

Table 46–3 lists a variety of clinical situations that modify normal maintenance water losses. The skin can be the source of very significant water loss. This is commonly seen in neonates, especially premature infants, who are under radiant warmers or who are receiving phototherapy. Premature infants can have insensible losses of 100–200?mL/kg/24?hr. Burns can result in massive losses of water and electrolytes and there are specific guidelines for fluid management in children with burns (see Chapter 62). Sweat losses of water and electrolytes, especially in a warm climate, can also be significant. Children with cystic fibrosis have increased sodium losses from the skin. Some children with pseudohypoaldosteronism also have increased

cutaneous salt losses.

Fever increases evaporative losses from the skin. These losses are somewhat predictable, leading to a 10–15% increase in maintenance water needs for each 1°C increase in temperature above 38°C. These guidelines are for a patient with a persistent fever; a 1-hr fever spike does not cause an appreciable increase in water needs.

Tachypnea or a tracheostomy increases evaporative losses from the lungs. A humidified ventilator causes a decrease in insensible losses from the lungs and can even lead to water absorption via the lungs. Thus, a ventilated patient has a decrease in maintenance water requirements. A mist tent decreases evaporative losses from both the skin and the lungs. Unfortunately, in all of these situations, it is difficult to quantify the changes that take place in the individual patient.

Replacement Fluids.

The gastrointestinal (GI) tract is potentially a source of considerable water loss. GI water losses are accompanied

TABLE 46-3 -- **Adjustments in Maintenance Water**

Source	Causes of Increased Water Needs	Causes of Decreased Water Needs
Skin	Radiant warmer	Mist tent
	Fever	
	Sweat	
	Burns

	Tracheostomy	Mist tent
Gastrointestinal tract	Diarrhea	
	Emesis	
	Nasogastric suction	
Renal	Polyuria	Oliguria/anuria
Miscellaneous	Surgical drain	Hypothyroidism
	Third spacing	

by electrolytes and thus may cause disturbances in hydration and electrolyte concentrations. GI losses are often associated with loss of potassium, leading to hypokalemia. Because of the high bicarbonate concentration in stool, children with diarrhea usually develop a metabolic acidosis, which may be accentuated if volume depletion causes hypoperfusion and a concurrent lactic acidosis. In contrast, emesis or losses from an NG tube cause a metabolic alkalosis.

The general strategy for responding to GI losses is the same for all situations. GI losses of water and electrolytes are usually quite small. Therefore, all GI losses are considered excessive and the increase in the water requirement is equal to the volume of fluid losses. Because GI losses can be precisely measured, it is possible to add the GI losses to the calculated maintenance water to determine the adjusted water requirement. The added electrolyte requirements are equal to the GI electrolyte losses. GI losses are best managed by using an appropriate replacement solution.

It is impossible to predict the losses for the next 24?hr. Thus, it is better to replace excessive GI losses as they happen. The child should receive an appropriate maintenance fluid that does not consider the GI losses. The losses should then be replaced as they occur using a solution with the same approximate electrolyte concentration as the GI fluid. The losses are usually replaced every 1–6?hr depending on the rate of loss, with very rapid losses being replaced more frequently. For example, 200?mL of NG output accumulates over 4?hr. The patient is given 200?mL of replacement solution at a rate of 50?mL/24?hr over the next 4?hr. Any NG output from the 4?hr when the patient is receiving the 200?mL is given over the subsequent 4?hr. If the NG losses increase, it may be necessary to provide the replacement solution more frequently, such as every 1–2?hr, in order to avoid dehydration.

Diarrhea is a common cause of fluid loss in children. It can cause dehydration and electrolyte disorders. In the patient with significant diarrhea and a limited ability to take oral fluid, it is important to have a plan for replacing excessive stool losses. The volume of stool should be measured and an equal volume of replacement solution should be given. The electrolyte composition of a replacement solution is always best determined by measuring the electrolyte content of the fluid that is being replaced. There is, however, data on the average electrolyte composition of diarrhea in children (Box 46–5). Using this information, it is possible to design an appropriate replacement solution. The solution shown in Box 46–5 replaces stool losses of sodium, potassium, chloride, and bicarbonate. Each milliliter of stool should be replaced by 1?mL of this solution. The average electrolyte composition of diarrhea is just an average, and there may be considerable variation. It is therefore advisable to consider measuring the electrolyte composition of a patient's diarrhea, particularly if the amount of diarrhea is especially excessive or the patient's serum electrolytes are problematic.

Loss of gastric fluid, either via emesis or NG suction, is also likely to cause dehydration in that most such patients have impaired oral intake of fluids. Electrolyte disturbances, particularly hypokalemia and metabolic alkalosis, are also common. These

Replace stool mL/mL every 1–6?hr

complications can be avoided by judicious use of a replacement solution. The electrolyte composition of gastric fluid is variable, with significant fluctuation during the course of the day. Moreover, H_2 -receptor antagonists and hydrogen pump inhibitors alter gastric electrolytes. The composition of gastric fluid shown in Box 46–6 serves as a useful starting point for designing a replacement solution. Again, direct measurement of gastric electrolytes provides the most precise approach.

Patients with gastric losses frequently develop hypokalemia, although the potassium concentration of gastric fluid is relatively low. The associated urinary loss of potassium is an important cause of hypokalemia in this situation (see Chapter 45). These patients may need additional potassium either in their maintenance fluids or in their replacement fluids to compensate for prior or ongoing urinary losses. Proper hydration of the patient, by decreasing aldosterone synthesis, lessens the urinary potassium losses.

Urine output is normally the largest cause of water loss. Diseases such as renal failure and the syndrome of inappropriate antidiuretic hormone can lead to a decrease in urine volume. The patient with oliguria or anuria has a decreased need for water and electrolytes; continuation of maintenance fluids produces fluid overload. In contrast, other conditions produce an increase in urine volume. Postobstructive diuresis, the polyuric phase of acute tubular necrosis, diabetes mellitus, and diabetes insipidus are examples. The patient must receive more than standard maintenance fluids when the urine output is excessive, else the patient will become dehydrated. The electrolyte losses in patients with polyuria are variable. In diabetes insipidus, the urine electrolyte concentration is usually low, whereas children with diseases such as juvenile nephronophthisis or obstructive uropathy usually have increased losses of both water and sodium.

The approach to decreased or increased urine output is similar (Box 46–7). The patient receives a maintenance fluid that replaces insensible losses. This is accomplished by running this fluid at one third of the normal maintenance rate. Replacing insensible losses in the anuric child will theoretically maintain an even fluid balance, with the caveat that one third of maintenance fluids is an estimate of insensible losses. In the individual patient, this rate may need to be adjusted based on monitoring of the patient's weight and hydration status. Most children with renal insufficiency receive little or no potassium because the kidneys are the principal site for potassium excretion.

For the oliguric child it is important to add a urine replacement solution to prevent dehydration. This is especially important in the patient with acute renal failure because output may slowly increase, which could lead to dehydration and a worsening of renal failure if the patient is left on insensible fluids. A replacement solution of ½ NS is usually appropriate initially, although its composition may need to be adjusted if urine output increases significantly.

The child with polyuria should also be placed on insensible fluids plus urine replacement. This avoids trying to calculate the volume of urine output that is “normal” so that the patient can be given replacement fluid for the excess. In these patients, the urine output is by definition excessive, and it is important to

measure the sodium and potassium concentration of the urine to help in formulating the urine replacement solution.

Surgical drains and chest tubes can produce measurable fluid output. These losses should be replaced when they are significant. They can be measured and replaced with an appropriate replacement solution as they occur. Third space losses are due to a shift of fluid from the intravascular space into the intersitial space. These losses cannot be easily quantitated. Nonetheless, third space losses can be massive and lead to intravascular volume depletion, despite the patient's weight gain and edema. Replacement of third space fluid is empirical but should be anticipated in patients who are at risk, such as children who have had abdominal surgery. Third space losses and chest tube output are isotonic and, thus, usually require replacement with an isotonic fluid such as normal saline or Ringer lactate. Adjustments in the amount of replacement fluid for third space losses are based on continuing assessment of the patient's intravascular volume status. Protein losses from chest tube drainage can be significant, occasionally necessitating that 5% albumin be used as a replacement solution.

Chapter 47 - Deficit Therapy

Dehydration, frequently the result of diarrhea, is a common problem in children. Most cases can be managed with oral rehydration, which is discussed in Chapter 48 . This chapter focuses on the child who requires intravenous therapy, even though many of the same principles are used in oral rehydration.

Clinical Manifestations.

The first step in caring for the child with dehydration is to assess the degree of dehydration. This dictates both the urgency of the situation and the volume of fluid needed for rehydration. Box 47–1 summarizes the clinical features that are present with varying degrees of dehydration.

Box 47-1. Clinical Evaluation of Dehydration

Mild dehydration (3–5%): normal or increased pulse, decreased urine output, thirsty, normal physical examination

Moderate dehydration (7–10%): tachycardia, little or no urine output, irritable/lethargic, sunken eyes and fontanel, decreased tears, dry mucous membranes, mild tenting of the skin, delayed capillary refill, cool and pale

Severe dehydration (10–15%): rapid and weak pulse, decreased blood pressure, no urine output, very sunken eyes and fontanel, no tears, parched mucous membranes, tenting of the skin, very delayed capillary refill, cold and mottled

The infant with mild dehydration has few clinical signs or symptoms. The infant may be thirsty; the alert parent may notice a decline in urine output. The history is most helpful; there is a narrative describing fluid loss. Such an infant is considered 5% dehydrated. The infant with moderate dehydration has clear physical signs and symptoms. The intravascular space is depleted as evidenced by an increased heart rate and limited urine output. This patient is about 10% dehydrated and needs fairly prompt intervention. The infant with severe dehydration is gravely ill. The decrease in blood pressure indicates that vital organs may be receiving inadequate perfusion. Immediate and aggressive intervention is necessary. This child is approximately 15% dehydrated. If possible, the child with severe dehydration should receive intravenous therapy. For older children and adults, mild, moderate, and severe dehydration represent 3%, 6%, and 9%, respectively, of body weight lost. This difference is because water is a higher percentage of body weight in infants (see Chapter 45). For all patients, clinical assessment of dehydration is only an estimate, and thus the patient must be continually re-evaluated during therapy. Moreover, the degree of dehydration tends to be underestimated in hypernatremic dehydration because the movement of water from the intracellular space to the extracellular space helps to preserve the intravascular volume. The opposite occurs with hyponatremic dehydration; dangerous intravascular volume depletion can occur with less severe fluid deficits.

The history usually points to the etiology of the dehydration and may predict whether the patient will have a normal sodium concentration (isotonic dehydration), hyponatremic dehydration, or hypernatremic dehydration. The neonate with dehydration due to poor intake of breast milk often has hypernatremic dehydration. Hypernatremic dehydration is likely in any child with losses of hypotonic fluid and poor water intake such as may occur with diarrhea and poor oral intake due to anorexia or emesis. In contrast, hyponatremic dehydration occurs in the child with diarrhea who is taking in large quantities of low salt fluid such as water or diluted formula.

Some children with dehydration are appropriately thirsty, but in others the lack of intake is part of the pathophysiology of the dehydration. Similarly, even though decreased urine output is present in most children with dehydration, good urine output may be deceptively present if a child has an underlying renal defect such as diabetes insipidus or a salt-wasting nephropathy, or in infants with hypernatremic dehydration.

Physical examination findings are usually proportional to the degree of dehydration. Parents may be helpful when assessing the child for the presence of sunken eyes because this finding may be subtle. Pinching and gently twisting the skin of the abdominal or thoracic wall detects tenting of the skin. Tented skin remains in a pinched position rather than springing quickly back to normal. It is difficult to properly assess tenting of the skin in premature infants or severely malnourished children. Activation of the sympathetic nervous system causes tachycardia in children with intravascular volume depletion; diaphoresis may also be present. Postural changes in blood pressure are often helpful for evaluating and assessing the response to therapy in children with dehydration. Tachypnea in children with dehydration may be present secondary to a metabolic acidosis from stool losses of bicarbonate or due to lactic acidosis from poor tissue perfusion.

Laboratory Findings.

A variety of laboratory findings are useful for evaluating the child with dehydration. The serum sodium concentration determines the type of dehydration. Metabolic acidosis may be due to stool bicarbonate losses in children with diarrhea, secondary renal insufficiency, or lactic acidosis from decreased tissue perfusion. The anion gap is useful for differentiating among the various causes of a metabolic acidosis (see Chapter 45). In contrast, emesis or nasogastric losses usually cause a metabolic alkalosis. The serum potassium concentration may be low as a result of diarrheal losses. In children with dehydration due to emesis, the combination of gastric potassium losses, metabolic alkalosis, and urinary potassium losses all contribute to hypokalemia. In contrast, metabolic acidosis, which causes a shift of potassium into cells, and renal insufficiency may lead to hyperkalemia. There is often a combination of mechanisms present and thus it may be difficult to predict the child's acid-base status or serum potassium by the history alone.

Blood urea nitrogen (BUN) and serum creatinine concentration are useful in assessing the child with dehydration. Volume depletion without renal insufficiency may cause a disproportionate increase in the BUN with little or no change in the creatinine concentration. This is secondary to increased passive reabsorption of urea in the proximal tubule due to appropriate renal conservation of sodium and water. This increase in the BUN with moderate or severe dehydration may be absent or blunted in the child with poor protein intake in that urea production is dependent on protein degradation. Conversely, the BUN may be disproportionally increased in the child with increased urea production, as occurs in the child with a gastrointestinal bleed or the child who is receiving glucocorticoids, which increase catabolism. A significant elevation of the creatinine concentration suggests renal insufficiency, although a false elevation in the creatinine can occur in the presence of ketoacidosis. Acute tubular necrosis due to volume depletion is the most common etiology of renal insufficiency in a child with volume depletion, but occasionally the child may have previously undetected chronic renal insufficiency or an alternative explanation for the acute renal failure. For example, renal vein thrombosis is a well-described sequelae of severe dehydration in infants; possible findings include thrombocytopenia and hematuria (see Chapter 512.3). The baseline normal creatinine concentration increases with age (see Fig. 500–6) and thus a normal adult creatinine concentration of 1?mg/dL may indicate significant renal insufficiency in an infant. The BUN and creatinine concentration are dependent on the timing of the disease process. Urea and creatinine are waste products that build up gradually with decreased renal excretion. A child with acute, severe dehydration may have only a minimal elevation of the serum creatinine concentration despite marked renal insufficiency; the creatinine concentration will increase over time.

Urinalysis is most helpful in the measurement of urine specific gravity, which is usually elevated in cases of significant dehydration but returns to normal after rehydration. Although infants have a reduced ability to concentrate the urine, even those who are a few weeks of age can show a clear elevation in specific gravity with significant dehydration. A specific gravity less than 1.020 indicates mild or no dehydration or indicates a urinary concentrating defect, as in chronic renal disease or primary or secondary diabetes insipidus. With dehydration, urinalysis may show hyaline and granular casts, a few white cells and red cells, and 30–100?mg/dL of

proteinuria. These findings are not usually associated with significant renal pathology, and they remit with therapy.

Hemoconcentration causes an increase in the hematocrit, hemoglobin, and serum proteins in dehydration. These values normalize with rehydration. A normal hemoglobin concentration during acute dehydration may mask an underlying anemia. A decreased albumin in a dehydrated patient suggests a chronic disease, such as malnutrition, nephrotic syndrome, or liver disease, or an acute process, such as capillary leak. An acute or chronic protein-losing enteropathy may also cause a low serum albumin concentration.

Calculation of Deficits.

The child with dehydration has lost water; there is almost always a concurrent loss of sodium and potassium. Most patients have isotonic dehydration and therefore have normal serum sodium values. The guidelines in Box 47–2 are used for calculating the deficits in isotonic dehydration due to gastroenteritis.

The water deficit is the percent dehydration multiplied by the patient's weight. The sodium and potassium deficits are derived from the water deficit (see Box 47–2).

Approach to Dehydration.

The child with dehydration requires acute intervention to ensure that there is adequate tissue perfusion. This requires restoration of the intravascular volume with an isotonic solution such as normal saline (NS) or Ringer lactate. The child is given a fluid bolus, usually 20?mL/kg, over about 20?min. The child with mild dehydration does not usually require a fluid bolus. In contrast, the child with severe dehydration may require multiple fluid boluses and may need to receive the boluses at a faster rate.

Blood, 5% albumin, and plasma are occasionally used for fluid boluses. In general, however, normal saline is satisfactory, with both less infectious risk and lower cost. Blood transfusion is indicated in the child with significant anemia or blood loss. Plasma is useful for children with a coagulopathy. The child with hypoalbuminemia may benefit from 5% albumin, although there is evidence that albumin infusions increase mortality in adults.

The initial rehydration is complete when the child has an adequate intravascular volume. Typically, the child will have some general clinical improvement, including a lower heart rate, a normalization of the blood pressure, improved perfusion, and a more alert affect.

When there is adequate intravascular volume, it is appropriate to plan the fluid therapy for the next 24?hr. The general approach is outlined in Box 47–3 . In isotonic dehydration, the entire fluid deficit is corrected over 24?hr. The child receives normal maintenance fluids and the fluid deficit. The total amount of water and electrolytes are added together and then an appropriate fluid is selected. For the patient with isotonic dehydration, D5 ½ normal saline with 20?mEq/L KCl is usually an appropriate fluid. For a child weighing less than 10–20?kg with only mild dehydration, a reduction of the sodium concentration is usually reasonable (¼ NS) because the majority of the administered fluid is maintenance fluid. Children with mild dehydration do not require intravenous therapy unless enteral therapy is not possible (see Chapter 48). As detailed herein, the potassium concentration may need to be decreased or, less commonly, increased depending on the clinical situation. Potassium is not usually included in the intravenous fluids until the patient voids. Half of the total fluid is given over the first 8?hr; previous boluses are subtracted from this volume. The remainder is given over the next 16?hr.

It is important to consider ongoing fluid losses of the patient. For example, the child with copious diarrhea must receive an additional replacement solution, or the rehydration will not be complete (see Chapter 46).

Monitoring and Adjusting Therapy.

The formulation of a plan for correcting a child's dehydration is only the beginning of management. All calculations in fluid therapy are only approximations. This is especially true with the assessment of percent dehydration. It is equally important to monitor the patient during treatment and to modify therapy based on the clinical situation. The cornerstones of patient monitoring are listed in Box 47–4 . The patient's vital signs are useful indicators of intravascular volume status. The child with a decreased blood pressure and an increased heart rate will probably benefit from a fluid bolus. The central venous pressure is an excellent indicator of fluid status in the critically ill child.

The patient's intake and output are critically important in the dehydrated child. The child who, after 8?hr of therapy, has more output than input due to continuing diarrhea needs to be placed on a replacement solution. See Chapter 46 guidelines for selecting an appropriate replacement solution. The urine output and urine specific gravity are useful for evaluating the success of therapy. The presence of a good urine output indicates that rehydration has been successful. This is supported by a decreasing urine specific gravity. For example, if the urine specific gravity is less than 1.005 and the patient is clinically well hydrated, it may be appropriate to decrease the intravenous fluid rate.

The presence of signs of dehydration on physical examination suggests the need for continued rehydration. In contrast, signs of fluid overload, such as edema or pulmonary congestion, are present in the child who is overhydrated. An accurate daily weight measurement is critical for management of the dehydrated child. There should be a gain in weight during successful therapy.

At least daily electrolyte measurements are appropriate for any child who is receiving intravenous rehydration. These children are at risk for disorders of sodium, potassium, and

ELECTROLYTES

acid-base. It is always important to look at trends. For instance, a sodium value of 144 is normal. Yet, if the sodium concentration was 136?mEq/L 12?hr earlier, then there is a distinct risk that the child will be hypernatremic in 12 or 24?hr. It is advisable to be proactive in adjusting fluid therapy.

Both hypokalemia and hyperkalemia are potentially serious (see Chapter 45). Because dehydration can be associated with acute renal failure and hyperkalemia, potassium is withheld from intravenous fluids until the patient has voided. The potassium concentration in the patient's intravenous fluids is not rigidly prescribed. Rather, the patient's serum potassium and underlying renal function are used to modify the potassium delivery. For example, the patient with an elevated creatinine and a potassium level of 5.0 does not receive any potassium until the serum potassium decreases. Conversely, the patient with a potassium level of 2.5 may require additional potassium.

Metabolic acidosis can be severe in dehydrated children. Even though normal kidneys will eventually correct this problem, it is often reasonable to accelerate this process by replacing a portion of the patient's intravenous sodium chloride with sodium bicarbonate or sodium acetate. Adding sodium bicarbonate or sodium acetate to the patient's calculated rehydration solution, without reducing the sodium chloride concentration, could cause hypernatremia as a result of the high sodium load. Base therapy is indicated in the child with a metabolic acidosis and kidneys that are incapable of excreting acid (i.e., the child with renal insufficiency or renal tubular acidosis). In contrast, in the child with a lactic acidosis from hypoperfusion, restoration of intravascular volume permits metabolism of lactate into bicarbonate and thus excessive administration of base may produce a metabolic alkalosis.

The serum potassium level is modified by the patient's acid base status. Acidosis increases the serum potassium by causing intracellular potassium to move into the extracellular space. Thus, as acidosis is corrected, the potassium concentration decreases. Again, it is best to anticipate this problem and to monitor the serum potassium concentration and adjust potassium administration appropriately.

Hyponatremic Dehydration.

The pathogenesis of hyponatremic dehydration is usually due to a combination of sodium and water loss and water retention to compensate for the volume depletion. The patient has a pathologic increase in fluid loss, and this fluid contains sodium. However, most fluid that is lost has a lower sodium concentration, so patients with only fluid loss would have hypernatremia. For example diarrhea has, on average, a sodium concentration of 50?mEq/L.

Hypernatremia does not occur because the patient drinks a low sodium containing fluid such as water or formula. By replacing diarrheal fluid with a sodium concentration of 50?mEq/L with water, which has almost no sodium, there is a reduction in the serum sodium concentration. Furthermore, the volume depletion stimulates synthesis of antidiuretic hormone, resulting in reduced renal water excretion. Hence, the body's usual mechanism for preventing hyponatremia, renal water excretion, is blocked. The risk of hyponatremia is further increased if the volume depletion is due to loss of fluid with a higher sodium concentration, as may occur with renal salt wasting, third space losses, or diarrhea with a high sodium content (e.g., cholera).

Hyponatremic dehydration produces more substantial intravascular volume depletion due to the shift of water from the extracellular space into the intracellular space. In addition, some patients develop symptoms, predominantly neurologic, from the hyponatremia (see Chapter 45).

The initial goal in treating hyponatremia is correction of intravascular volume depletion with isotonic fluid (NS or Ringer lactate). Hyponatremic dehydration requires replacement of sodium and water losses. The following formula can be used to calculate a patient's sodium deficit:

where $[Na^+]_d$ = desired sodium concentration, $[Na^+]_i$ = initial sodium concentration, and Wt = weight in kilograms.

When calculating the sodium deficit, it is important to choose an appropriate desired sodium concentration. In general, it is not necessary to increase the sodium beyond

135?mEq/L; “overcorrection” is associated with an increased risk of central pontine myelinolysis (CPM). The risk of CPM also increases with overly rapid correction of the serum sodium concentration, so it is important to avoid increasing the sodium by more than 12?mEq/L each 24?hr. Most patients with hyponatremic dehydration do well with the same basic strategy that is outlined in Box 47–3 . Despite the increased sodium deficit in these patients compared with patients with isotonic dehydration, D5 ½ NS with 20?mEq/L KCl is usually effective. As with isotonic dehydration, half the fluid can be administered over the first 8?hr. Again, potassium delivery is adjusted based on the initial serum potassium and the patient's renal function. Potassium is not given until the patient voids.

The patient's sodium concentration is monitored to ensure appropriate correction and the sodium concentration of the fluid is adjusted appropriately. Patients with ongoing losses require an appropriate replacement solution (see Chapter 46). Patients with neurologic symptoms (e.g., seizures) from hyponatremia need to receive an acute infusion of hypertonic (3%) saline to rapidly increase the serum sodium concentration (see Chapter 45).

Hypernatremic Dehydration.

Hypernatremic dehydration is the most dangerous form of dehydration due to complications of hypernatremia and of therapy. Hypernatremia can cause serious neurologic damage, including hemorrhages and thrombosis. This appears to be secondary to movement of water from the brain cells into the hypertonic extracellular fluid, causing brain cell shrinkage and tearing blood vessels within the brain (see Chapter 45).

The movement of water from the intracellular space to the extracellular space during hypernatremic dehydration protects the intravascular volume. Thus, children with hypernatremia often appear less ill than children with a similar degree of isotonic dehydration. Urine output may be preserved longer and there may be less tachycardia. Unfortunately, the milder manifestations often lead to children with hypernatremic dehydration being brought to medical attention with more profound dehydration.

Children with hypernatremic dehydration are often lethargic, but irritable when touched. Hypernatremia may cause fever, hypertonicity, and hyperreflexia. More severe neurologic symptoms may develop if cerebral bleeding occurs.

The treatment of hypernatremic dehydration may cause significant morbidity and mortality. There is generation of idiogenic osmoles within the brain during the development of hypernatremia. These idiogenic osmoles increase the osmolality within the cells of the brain, providing protection against brain cell shrinkage caused by movement of water out of cells into the hypertonic extracellular fluid. However, these idiogenic osmoles dissipate slowly during correction of hypernatremia. With overly rapid lowering of the extracellular osmolality during correction of hypernatremia, there may be an osmotic gradient created that causes water movement from the extracellular space into the cells of the brain, producing cerebral edema. Symptoms of the resultant cerebral edema can range from seizures to brain herniation and death.

To minimize the risk of cerebral edema during correction of hypernatremic dehydration, the serum sodium concentration

---

should not decrease more than 12?mEq/L every 24?hr. Severe hypernatremic dehydration may need to be corrected over 2–4 days (Box 47–5).

The initial management of hypernatremic dehydration requires restoration of the intravascular volume with normal saline. Ringer lactate should not be used because it is more hypotonic than normal saline and may cause too rapid a decrease in the serum sodium concentration, especially if multiple fluid boluses are necessary.

To avoid cerebral edema when correcting hypernatremic dehydration, the fluid deficit is corrected slowly. The rate of correction depends on the initial sodium concentration (see Box 47–5). Unlike patients with isotonic or hyponatremic dehydration, the fluid is not run at a faster rate during the first 8?hr. There is not general agreement on the choice of fluid or the rate of fluid for correcting hypernatremic dehydration. The choice and rate of fluid administration are not nearly as important as vigilant monitoring of the serum sodium concentration and adjustment of the therapy based on the result (see Box 47–5). The rate of decrease of the serum sodium concentration is roughly related to the “free water” delivery, although there is considerable variation between patients. Free water is water without sodium. For example, NS contains no free water, ½ NS is 50% free water, and water is 100% free water. In general, smaller patients, to achieve the same decrease in the sodium concentration, tend to need higher amounts of free water delivery per kilogram because of higher insensible fluid losses. D5 ¼ NS is probably an appropriate starting solution for a neonate with hypernatremic dehydration whereas D5 ½ NS may be a better choice in a 3-year-old. Occasionally, fluid with a lower sodium concentration than D5 ¼ NS or a higher sodium concentration than D5 ½ NS is necessary. A child with dehydration due to pure free water loss, as usually occurs with diabetes insipidus, usually needs a more hypotonic fluid than a child with depletion of both sodium and water due to diarrhea.

Adjustment in the sodium concentration of the intravenous fluid is the most common approach for modifying the rate of decrease in the serum concentration (see Box 47–5). For difficult patients with severe hypernatremia, having two intravenous solutions (e.g., D5 ¼ NS and D5 ½ NS, both with the same concentration of potassium) at the bedside can facilitate this approach by allowing for rapid adjustments of the rates of

Box 47-5. Treatment of Hypernatremic Dehydration

Restore intravascular volume

Normal saline: 20?mL/kg over 20?min (Repeat until intravascular volume restored)

Determine the time for correction based on the initial sodium concentration

[Na]: 145–157?mEq/L: 24?hr

[Na]: 158–170?mEq/L: 48?hr

[Na]: 171–183?mEq/L: 72?hr

[Na]: 184–196?mEq/L: 84?hr

Administer fluid at a constant rate over the time for correction

Typical fluids: D5 1/4 NS or D5 1/2 NS (both with 20?mEq/L KCl unless contraindicated)

Typical rate: 1.25–1.5 times maintenance

Follow serum sodium concentration Adjust fluid based on clinical status and serum sodium concentration

Signs of volume depletion: administer NS (20?mL/kg)

Sodium decreases too rapidly

Decrease rate of intravenous fluid

Sodium decreases too rapidly

Increase sodium concentration of intravenous fluid, or

Decrease rate of intravenous fluid

Sodium decreases too slowly

Decrease sodium concentration of intravenous fluid, or

Increase rate of intravenous fluid

Replace ongoing losses as they occur

the two fluids. If the serum sodium concentration decreases too rapidly, the rate of D5 ½ NS can be increased and the rate of D5 ¼ NS can be decreased. Adjustment in the total rate of fluid delivery is another approach for modifying free water delivery. For example, if the serum sodium concentration is decreasing too slowly, the rate of the intravenous fluid can be increased, thereby increasing the delivery of free water. There is limited flexibility in modifying the rate of the intravenous fluid because patients generally should receive between 1.25 and 1.5 times the normal maintenance fluid rate. Nevertheless, in some situations this can be a helpful adjustment.

Because increasing the rate of the intravenous fluids increases the rate of decrease of the sodium concentration, signs of volume depletion are treated with additional fluid boluses. The serum potassium concentration and the level of renal function dictate the potassium concentration of the intravenous fluid; potassium is held until the patient voids. Patients with hypernatremic dehydration need an appropriate replacement solution if they have excessive losses (see Chapter 46).

Seizures are the most common manifestation of cerebral edema and result from an overly rapid decrease of the serum sodium concentration during correction of hypernatremic dehydration. Acutely, increasing the serum concentration via an infusion of 3% sodium chloride can reverse the cerebral edema. Each mL/kg of 3% sodium chloride increases the serum sodium concentration by approximately 1?mEq/L. An infusion of 4–6?mL/kg often results in resolution of the symptoms. This is similar to the strategy used for treating symptomatic hyponatremia (see Chapter 45).

In patients with severe hypernatremia, oral fluids must be used cautiously. For example, infant formula, because of its low sodium concentration, has a very high free water content, and, especially if added to intravenous therapy, may contribute to a rapid decrease in the serum sodium concentration. Less hypotonic fluid, such as an oral rehydration solution, may be more appropriate initially (see Chapter 48). If oral intake is allowed, its contribution to free water delivery must be taken into account and adjustment in the intravenous fluid is usually appropriate. Judicious monitoring of the serum sodium concentration is critical.

Chapter 48 - Fluid and Electrolyte Treatment of Specific Disorders

48.1 Acute Diarrhea and Oral Rehydration

Also see Chapters 287 and 321 .

Diarrhea continues to be a serious problem in many areas of the world and may be especially lethal when superimposed on malnutrition. Diarrhea results in large losses of water and electrolytes, especially sodium and potassium, and frequently is complicated by severe systemic acidosis. In approximately 70–80% of patients, the losses of water and sodium are proportionate, with *isotonic dehydration* developing. *Hyponatremic dehydration* is seen in approximately 10–15% of all patients with

diarrhea. It occurs when large amounts of electrolytes, especially sodium, are lost in the stool out of proportion to fluid losses. It occurs more frequently with bacillary dysentery or cholera. Hyponatremia may develop or worsen if during diarrhea there is a considerable oral intake of low-electrolyte or electrolyte-free fluids.

Disproportionately large net losses of water compared with losses of electrolytes result in *hypernatremic dehydration.* It is seen in 10–20% of patients with diarrhea and may occur during the course of diarrhea when oral homemade electrolyte solutions with high concentrations of salt are administered or when infants are fed boiled skim milk, which produces a high renal solute load and increased urinary water losses. The potential for hypernatremia also increases with increased evaporative water loss from fever, high environmental temperatures, and hyperventilation and with decreased availability of free water.

The administration of intravenous fluids for treating profound dehydration from severe diarrhea is discussed in Chapter 47 . Mild to moderate dehydration from diarrhea of any cause can be treated effectively in a wide range of age groups using a simple oral glucose-electrolyte solution (Table 48–1). These solutions rely on the coupled transport of sodium and glucose in the intestine. Oral rehydration therapy is used in many countries and has significantly reduced the morbidity and mortality from acute diarrhea and lessened diarrhea-associated malnutrition. Oral rehydration is underused in developed countries, but it should be attempted for most patients with mild to moderate diarrheal dehydration when adequate supervision is available.

Oral rehydration therapy is less expensive than intravenous therapy and has a lower complication rate. Intravenous therapy may still be required for patients with severe dehydration; those with uncontrollable vomiting; those unable to drink because of extreme fatigue, stupor, or coma; or those with gastric or intestinal distention.

As a guideline for oral rehydration, 50?mL/kg of the oral rehydration solution (ORS) should be given within 4?hr to patients with mild dehydration and 100?mL/kg over 4?hr to those with moderate dehydration. Supplementary ORS is given to replace ongoing losses from diarrhea or emesis. An additional 10?mL/kg of ORS is given for each stool. Fluid intake should be decreased if the patient appears fully hydrated earlier than expected or if the patient develops periorbital edema. Breast-feeding should be allowed after rehydration in infants who are breast-fed; in other patients, their usual formula, milk, or feeding should be offered after rehydration. Along with its nutritional benefits, early refeeding decreases the duration of diarrhea. Most children can tolerate a lactose-containing formula, although some children benefit from a lactose free formula if malabsorption is present.

Vomiting may occur during the first 2?hr of administration of ORS, but it usually does not prevent successful oral rehydration if the ORS is given in small amounts at short intervals (a teaspoon every 1 to 2?min). Emesis usually lessens over time. The volume of ORS can be slowly increased, with an increasing

TABLE 48.1-1 -- **Composition of Oral Rehydration Solutions**

WHO = World Health Organization.

* *Rice syrup solids are the carbohydrate source.*

interval between feedings. If sustained and severe vomiting occurs, intravenous therapy should be instituted. The patient's progress should be assessed frequently and changes in body weight monitored, if possible, to determine the degree of rehydration.

When rehydration is complete, maintenance therapy should be started. Patients with mild diarrhea usually can then be treated at home using 100?mL of ORS/kg/24?hr until the diarrhea stops. Breast-feeding or supplemental water intake should be maintained. Patients with more severe diarrhea require continued supervision. The volume of ORS ingested should equal the volume of stool losses. If stool volume cannot be measured, an intake of 10–15?mL of ORS/kg/hr is appropriate.

There is a significant difference in the sodium concentration between the World Health Organization (WHO) solution and the commercially available solutions that are generally used in the United States (see Table 48–1). Low-sodium solutions were advocated because hypernatremia was seen frequently in the United States when oral electrolyte solutions with sodium concentrations of 50?mEq/L or more were used to treat infantile diarrhea. However, extensive use of ORS in many developing countries has shown hypernatremia to be a rare complication, probably because ORS has been used primarily for rehydration (the major previous role for oral therapy was to prevent dehydration or for maintenance); because large amounts of water are ingested in addition to ORS, often a 2:1 ratio of ORS to H_2O; and because ORS has been administered under close supervision by trained personnel. The WHO ORS has also been effective in treating acute diarrheal illnesses in well-nourished children in developed countries. There is a risk of hypernatremia with the WHO ORS if it is used as a maintenance solution without supplemental water or formula. Several commercially available electrolyte solutions for oral use have been reformulated with a sodium concentration of approximately 50?mEq/L. These solutions are effective in the treatment of mild to moderate dehydration. Reduced osmolality solutions (primarily reduced sodium and glucose) are associated with reduced stool output.

48.2 Diarrhea in Chronically Malnourished Children

Severe malnutrition complicated by diarrheal dehydration is common in tropical and subtropical countries and occurs occasionally in the temperate zones. Therapy should be adapted to meet the specific disturbances in body composition characteristic of the dehydrated *and* malnourished infant, in whom there appears to be an overexpansion of the extracellular space, accompanied by extracellular and presumably intracellular hypo-osmolality. Serum sodium, potassium, and magnesium levels tend to be low, and tetany occasionally may result from a magnesium or calcium deficiency. Serum protein levels are frequently less than 3.6?g/dL. The sodium content of muscle is high; potassium and magnesium contents are low. The

electrocardiogram (ECG) frequently shows tachycardia, low amplitude, and flat or inverted T waves. Cardiac reserve seems lowered, and heart failure is a common complication.

Despite clinical signs of dehydration and reduced body water, urinary osmolality may be low in the chronically malnourished child. This defect in renal concentration may result from the relative absence of urea to contribute to a hypertonic milieu in the renal papillae, a defect associated with a low dietary protein intake, and resulting in a failure of tubular conservation of water. However, the glomerular filtration rate is low, resulting in a smaller loss of water than would otherwise be expected. Renal concentrating ability returns after several days of high-protein feedings. The renal acidifying ability is also limited in patients with malnutrition.

Survival of the malnourished infant with diarrhea is limited by caloric deficit to a greater extent than by water and electrolyte deficit. Reparative calories can be given by slow drip through an indwelling nasogastric tube in conjunction with oral or, when necessary, intravenous rehydration. If appetite is poor and vomiting and gastric distention are absent, feeding is begun early (30–40?cal/kg/24?hr), given by slow intragastric drip. Increases to 50–100?cal/kg/24?hr and 1–2?g of protein/kg/24?hr are made in a few days. Ad libitum intake should be permitted in the succeeding days and weeks, up to 250–300?cal/kg/24?hr, and the diet should include an adequate supply of iron and copper.

Initial parenteral therapy in profound dehydration is designed to improve the circulation and expand extracellular volume. For patients with edema, the quantity of fluid and rate of administration may need to be readjusted from recommended levels to avoid pulmonary edema. Blood should be given if the patient is in shock and severely anemic. Potassium salts can be given early if the urine output is good. Clinical and ECG improvement may be more rapid with magnesium therapy. Seizures occurring during recovery from diarrhea complicating severe malnutrition may respond to magnesium.

48.3 Pyloric Stenosis

Also see Chapter 310.1 .

This condition exemplifies the correction of deficits associated with alkalosis. The therapy differs little from that for other causes of dehydration, except that potassium replacement should begin early, as soon as the child has urinated. These patients have a chloride-responsive metabolic alkalosis (see Chapter 45) and only volume repletion, via administration of sodium chloride and potassium chloride, will allow correction of the metabolic alkalosis. Correction of the hypochloremia and alkalosis by administering ammonium chloride without correcting the potassium deficit is not recommended.

Severe depletion of intracellular potassium results in the increased exchange of hydrogen ion for sodium in the distal nephrons of the kidney. The paradoxical presence of an acid urine with systemic alkalosis should be interpreted as signifying a marked potassium deficit and a need to increase the amount of potassium used for repletion.

It is not uncommon for deficits to be replaced and serum levels of electrolytes returned to normal within 6–12?hr. However, except in the mildly ill infant without signs of dehydration, it is preferable to delay surgery for at least 24–48?hr to achieve optimal readjustment of body functions. During this preparation period, adequate fluid therapy prevents dehydration, and the stomach may be decompressed by gentle suction.

48.4 Perioperative Fluids

Preoperatively, preparing a patient having no pre-existing deficit or in whom the deficit has been repaired consists mainly of supplying adequate carbohydrate for sustenance and protein sparing and the usual maintenance requirements of water and electrolytes. Young infants who are not vomiting should receive carbohydrate and electrolyte mixtures by mouth until 3?hr before the operation. Such fluids are readily absorbed from the gastrointestinal tract. Preparing the newborn involves certain unique hazards. Deficits of water and electrolytes from vomiting or from stasis caused by intestinal obstruction should be replaced before the surgery. In cases of intestinal obstruction, conjugated bilirubin may be deglucuronidated by intestinal enzymes; enterohepatic circulation of unconjugated bilirubin can then lead to high serum levels and kernicterus. Hypoprothrombinemia should be prevented by administering 1?mg of vitamin K.

During surgery, blood, plasma, saline, or other volume expanders may be given if blood loss, tissue trauma, third spacing, or excessive evaporative loss occurs. The magnitude of such losses is best judged by the experienced surgeon in the course of the procedure. *The most common error in administering parenteral fluid during and after surgery is excessive administration,* particularly of dextrose in water, rather than use of isotonic solutions. Under most circumstances, little to no potassium need be administered during this time, because extensive tissue trauma or anoxia may result in the release of large amounts of intracellular potassium, with the potential of causing hyperkalemia. If shock occurs, acute renal failure may ensue, impairing the ability to eliminate through the renal route large amounts of released potassium.

Postoperatively, fluid intake should be limited for 24?hr. Thereafter, the usual maintenance therapy is gradually resumed. The water intake should not exceed 85?mL/100?kcal metabolized, because of antidiuresis resulting from trauma, circulatory readjustment, general anesthesia, or narcotic pain relief, unless renal ability to concentrate the urine is limited, as in patients with sickle cell disease, chronic pyelonephritis, or obstructive uropathy. If the intake of water is not limited, whether given parenterally or orally, water intoxication may occur associated with severe hyponatremia and even fatal cerebral edema. This has been reported in post-tonsillectomy patients. Fluid therapy in the postoperative period largely depends on the complex but anticipated response of the body to trauma through modification of water and sodium excretion and the concomitant occurrence of complications from surgery. The patient's clinical condition dictates the final fluid and electrolyte requirements incurred as a result of these processes.

Postoperatively, some children have elevated blood antidiuretic hormone (ADH) levels due to syndrome of inappropriate ADH (SIADH) or to an appropriate response to fluid restriction and resultant volume contraction. If decreasing urine output after

surgery is the result of SIADH, the patient is euvolemic and has a normal circulatory status, stable to slightly increased weight, and an elevated urinary sodium excretion. If a child has oliguria related to third spacing and true depletion of intravascular volume, there is decreased urinary sodium excretion associated with clinical signs of hypovolemia, such as weight loss, tachycardia, changes in skin turgor and peripheral perfusion, and hypotension. Isotonic solutions are indicated in this setting.

Part 8 - The Acutely Ill Child

Chapter 49 - Evaluation of the Sick Child in the Office and Clinic

Paul L. McCarthy

The approaches to clinical data gathering for the well child evaluation are also useful for the sick child evaluation (see Chapter 6). There are many reasons for a sick child visit, but most are due to acute intercurrent infections, and often the child is febrile.

When evaluating an acutely ill, febrile child, the pediatrician must be aware of categorical statistics about the probable occurrence of serious illness, because one of the major goals of the sick child visit is to identify the seriously ill child who requires specific therapeutic intervention. The risk for and the cause of serious illness in the acutely febrile child vary depending on age. The infant in the first 3 mo of life is more susceptible to sepsis and meningitis caused by group B streptococci and gram-negative organisms. Infants in the first month of life are at highest risk. Urinary tract infections are more frequent in males; infants in this age group more often have an underlying anatomic abnormality of the urinary tract than do older children with urinary tract infections. As the infant matures beyond 3 mo, the bacterial pathogens that usually cause sepsis and meningitis are *Streptococcus pneumoniae, Haemophilus influenzae* type b (if the child is unimmunized or only partially immunized), and *Neisseria meningitidis*. Immunization against some serotypes of *S. pneumoniae* may reduce the occurrence of serious infections caused by that organism as has immunization against *H. influenzae* type b. After infancy, urinary tract infections are seen more often in females. Immunity develops rapidly to the common bacterial pathogens during the first 3–4 yr of life. *N. meningitidis* is the leading cause of bacterial meningitis. In children older than 36 mo, pharyngitis caused by group A streptococci is a common bacterial infection. *Mycoplasma pneumoniae* assumes increasing importance as a cause for pulmonary infiltrates in

children older than 5 yr of age. Serious illnesses documented in children in the first 3 yr of life who presented with fever and acute illnesses from a university hospital and private practice are shown in Table 49–1 . In other studies, urinary tract infections are the most common serious bacterial infections. Soft tissue infections may include cellulitis, osteomyelitis, and septic arthritis.

The acutely ill child with a serious illness is identified by careful observation, history taking, physical examination, appreciation of age and body temperature as risk factors, and the judicious use of screening laboratory tests. The physician can make informed decisions with the data about the need for more definitive laboratory tests (e.g., urine culture), therapy, and the advisability of hospital admission. Observation, history, and physical examination are integrated into the sick child evaluation; that is, as the child is being observed, historical data are gathered. History taking and observational assessment often continue as the physical examination is performed. If, for example, abdominal tenderness is found on examination, additional

From McCarthy PL: Acute infectious illness in children. Comp Ther 1988;14:51.

** Nonserious illness includes benign viral diseases such as roseola herpesvirus 6 or 7, enteroviruses, respiratory syncytial virus, influenza, metapneumovirus, parainfluenza, and rotavirus.*
† Includes cellulitis, osteomyelitis, and septic arthritis.

history about blood in the stool, cramping abdominal pain, and vomiting may be sought.

Observation is important in the evaluation of the acutely ill child. The child should be observed for specific evidence of a serious illness, such as grunting, which might indicate pneumonia or sepsis, or a bulging fontanel, which might indicate bacterial meningitis. *Most observational data that the pediatrician gathers during an acute illness should focus, however, on assessing the child's response to stimuli*. How does the child's crying respond to the parents' comforting? If sleeping, how quickly does the child awaken with a stimulus? Does the child smile when the examiner interacts with him or her? Assessing responses to stimuli, and often providing those stimuli, requires knowledge of normal responses for different age groups, the manner in which those normal responses are elicited, and to what degree a response might be impaired (see Chapter 6).

Sometimes the manner in which the child responds to stimuli is readily apparent. For example, the child may vocalize and smile as the examiner enters the room. At other times, more effort and more stimuli are needed to cause the child to act in a normal manner. Often the fussing, irritable child begins to look around and focus on the examiner when held and walked by the parent. This normal visual behavior is an important indicator of well-being. Thus, during observation, the pediatrician must be both clinically and developmentally oriented.

Six observation items and their scales (the Acute Illness Observation Scales) that have reliably and validly identified serious illness in febrile children are shown in Figure 49–1 . A normal finding is scored as 1, a moderate impairment as 3, and severe impairment as 5. The best possible score is 6 items × 1 = 6; the worst score is 6 items × 5 = 30. The chance of serious illness is 1–2% if the total score is 10 or less; if the score is more than 10, the risk of serious illness increases by at least 10-fold. It is not clear whether these scales can be used in the first 2–3 mo of life because infants may not have developed the skills required to score some of these items.

Figure 49-1 Acute Illness Observational Scales for use in clinical evaluation of the well and sick child. (From McCarthy PL, Sharpe MR, Spiesel SZ, et al: Observation scales to identify serious illness in febrile children. *Pediatrics* 1982;70:802, with permission.)

History taking is complex (see Chapters 6 and 17.1). Parents must transmit how a younger child has been "feeling." Parents should also provide information on a specific symptom, such as bloody diarrhea or cyanosis when coughing. The older child's perception of symptoms may reflect a developmentally immature understanding of causation. The examiner pursues the historical information provided by the parents or child to define the symptoms precisely. For example, if the complaint is blood in the stool, additional questions can be asked about other evidence of bowel inflammation, such as watery stools, mucus in the stools, or increased frequency of stooling. If the historical information indicates crying with defecation and streaks of blood on the outer portion of a hard stool, without other changes in the character or frequency of the stool, a diagnosis of a rectal fissure is tenable.

Questions should focus on those entities that are seen most commonly in acute febrile childhood illnesses. The more serious diagnoses are outlined in Table 49–1 .

Organ-specific questions are helpful, such as fast breathing, cyanosis, retraction, and wheezing with pneumonia, or pain, swelling, and pseudoparalysis with septic arthritis. Because most acute illnesses in children are caused by minor viral infections, specific questions about the epidemiology of the illness can offer important insights. Are there other children in the family with similar symptoms? Has the child had other illness exposures? Finally, it is important to be aware of any underlying chronic problems that might predispose the child to recurring infections or a serious acute illness; for example, the child with sickle cell anemia or AIDS is at increased risk for recurrent episodes of bacteremia. Benign viral illnesses may produce serious secondary consequences such as dehydration. Additional questions to assess hydration such as wet diapers, tears, or awakeness should be used to assess secondary complications.

The physical examination follows the same sequence for the well child (see Chapter 6). The examiner should be aware of and seek evidence of illnesses that might be present in the acutely ill child. Initially, it is best to seat the child on the parent's lap; the older child may be seated on the examination table. Vital signs are often overlooked but are quite valuable in assessing ill children. The degree of fever, the presence of tachycardia out of proportion to the fever, and the presence of tachypnea and hypotension all suggest a serious infection. In addition to the general level of interaction, color, and hydration, as assessed in the Acute Illness Observation Scales (see Fig. 49–1), the child's respiratory status is evaluated. This evaluation includes determining respiratory rate and noting any evidence of inspiratory

stridor, expiratory wheezing, grunting, or coughing. Evidence of increased work of breathing—retractions, nasal flaring, and use of abdominal musculature—is sought. Because acute infections in children are most often caused by viral infections, the presence of nasal discharge is noted. It is possible at this time to assess the skin for rashes. Frequently, viral infections cause an exanthematous eruption, and many of these eruptions are diagnostic (e.g., the reticulated rash and “slapped-cheek” appearance caused by parvovirus infections or the typical appearance of hand-foot-and-mouth disease caused by coxsackieviruses). The skin examination may also yield evidence of more serious infections (e.g., bacterial cellulitis or petechiae associated with bacteremia). Cutaneous perfusion should be assessed by warmth and capillary refill time. When the child is seated and is least perturbed, an assessment of fontanel tension can be completed; it can be determined if the fontanel is depressed, flat, or bulging. It is also important at this time to assess the child's willingness to move and ease of movement. Usually the child with meningitis will hold the neck stiffly and often cry when any attempt is made to move the neck, even during cuddling by the parent. This is termed *paradoxic irritability*. The child with cellulitis, osteomyelitis, or septic arthritis in an extremity will resist movement of that limb. The child with peritoneal inflammation will sit quietly and become irritable during movement. It is reassuring to see the child moving about on the parent's lap with ease and without discomfort.

During this initial portion of the physical examination, when the child is most comfortable, the heart and lungs are auscultated. In the acutely febrile child, because of the relatively frequent occurrence of respiratory illnesses, it is important to assess adequacy of air entry into the lungs, equality of breath sounds, and evidence of adventitial breath sounds, especially wheezes, rales, and rhonchi. The coarse sound of air moving through a congested nasal passage is frequently transmitted to the lungs. The examiner can become attuned to these coarse sounds by placing the stethoscope near the child's nose and then compensating for this sound as the chest is auscultated. The cardiac examination is completed next; findings such as pericardial friction rub, loud murmurs, or distant heart sounds may indicate an infectious process involving the heart. The eyes are examined to identify features that might indicate an infectious process. Often, viral infections result in a watery discharge or redness of the bulbar conjunctivae. Bacterial infection, if superficial, results in purulent drainage; if the infection is more deep-seated, tenderness, swelling, and redness of tissues surrounding the eye are present as well as proptosis, reduced acuity, and altered extraocular movement. The extremities may then be evaluated not only for ease of movement but also for the possibility of swelling, heat, or tenderness; such abnormalities may indicate focal infections.

The components of the physical examination that are more bothersome to the child are completed last. This is best done with the patient on the examination table. Initially, the neck is examined to assess for areas of swelling, redness, or tenderness, as may be seen in cervical adenitis. The neck is then flexed to evaluate suppleness; resistance to flexion is indicative of meningeal irritation. Both Kernig's and Brudzinski's signs may be sought at this time. In children younger than 18 mo, meningeal signs may not always be present with meningitis; if, however, they are present, the diagnostic implications are the same as for the child older than 18 mo. During examination of the abdomen, the diaper is removed. The abdomen is inspected for distention. Auscultation is performed to assess adequacy of bowel sounds, followed by palpation. It is often the case that the child fusses as the abdomen is auscultated and palpated. Every attempt should be made to quiet the child; if this is not possible, increased fussing as the abdomen is palpated may indicate tenderness, especially if this finding is reproducible. In addition to focal tenderness, palpation may elicit involuntary guarding or rebound; these findings indicate peritoneal irritation, as is seen in appendicitis. The inguinal area and genitals are then sequentially examined. In the febrile child, inguinal adenitis or a strangulated hernia may be the cause of fever. The child is then placed in the prone position, and abnormalities of the back are sought. The spine and costovertebral angle (CVA) areas are percussed to elicit any tenderness; such findings may be indicative of osteomyelitis or diskitis, and pyelonephritis, respectively.

The physical examination is completed by examining the ears and throat. These are usually the most bothersome parts of the examination for the child, and parents frequently can be helpful in minimizing head movement. The oropharyngeal examination is important to document the presence of enanthemas; these may be seen in many infectious processes, such as hand-foot-and-mouth disease caused by coxsackievirus. This portion of the examination is also important in documenting inflammation or exudates on the tonsils, which may be viral or bacterial.

At times, repeating portions of observational assessment and the physical examination is indicated. For example, if the child cried continuously during the initial clinical evaluation, the examiner may not be certain if this was caused by the high fever or stranger anxiety or is indicative of a serious illness. Continual crying also makes portions of the physical examination, such as auscultation of the chest, more difficult. Before a repeat assessment is performed, maneuvers to make the child as

comfortable as possible are indicated. Such maneuvers include reducing the fever with antipyretics and allowing the child to take a bottle. Because most children with fever do not have serious illnesses, repeated assessments are more likely to document normal findings. If, on the other hand, the child is persistently irritable, the possibility of serious illness increases.

The sensitivity of the carefully performed clinical assessment, observation, history, and physical examination for the presence of serious illness is approximately 90%. Careful data gathering is necessary in the observation, history, and physical examination, because each component of the evaluation is as effective as the others in identifying serious illness. Other data, however, should be sought to improve this sensitivity level. In the child with an acute febrile illness, the important supplemental data are age, body temperature, and screening laboratory tests. Febrile children in the first 3 mo of life have yet to achieve immunologic maturity and therefore are more susceptible to severe infections and to infections by unusual organisms. Thus, the febrile infant is at greater risk for serious illness than the child beyond 3 mo of age (see Chapter 162). In febrile children, the higher the fever, the greater the risk for serious illness. The risk of bacteremia in infants increases as the degree of fever increases; at 40°C (105°F) or more the risk is 7%. The limit of physiologic thermoregulation is 41.1°C (106°F); fevers in this range and higher indicate not only bacteremia but also possible central nervous system infection, pneumonia, or pathologic hyperthermia.

Screening laboratory tests may be helpful in identifying the febrile child at increased risk for selected serious illnesses. *S. pneumoniae* is currently the most common cause of occult bacteremia not associated with a focal soft tissue infection. A total white blood cell count of 15,000/mm^3 or more and/or absolute neutrophil count of 10,000/mm^3 or more, in addition to age 3–36 mo, higher grades of fever, or a more ill appearance, are indicators of increased risk for occult bacteremia caused by *S. pneumoniae*. A urinalysis and urine culture should be considered when the source of fever is not apparent, especially in females and uncircumcised males younger than 2 yr of age and all boys younger than 1 yr of age—the highest risk groups. The presence of leukocyte esterase, more than 5 white blood cells per high-power field on a spun urine specimen, or bacteria by Gram stain on an unspun urine specimen suggest a urinary tract infection, but the sensitivity of these indicators is, on average, only 75–85% and the urine culture is the definitive test. An elevated

C-reactive protein value may also distinguish bacterial from viral infections.

Diagnostic approach (see also Chapters 98 and 162): If the febrile child is older than 3 mo and appears well, if the history or physical examination does not suggest a serious illness, and if no age or temperature risk factors are present, the child may be followed expectantly. If otitis media is present, it should be treated. This profile applies to most children with acute infectious illnesses. If, on the other hand, the child appears ill or the history or physical examination suggests a serious illness, definitive laboratory tests appropriate for those findings are indicated (e.g., a chest radiograph for a child with grunting). The area of greatest controversy is whether laboratory studies are needed on the febrile child who appears well and has no abnormalities on history and physical examination but who is younger than 3 mo of age or whose temperature is high. Many would agree that a sepsis work-up is indicated in the febrile child younger than age 3 mo (see Chapters 98 and 162). Obtaining blood cultures in children older than 3 mo with higher grades of fever has gained increased acceptance.

If the physician feels comfortable in following as an outpatient the child in whom no specific diagnosis has been established, a follow-up examination often yields a diagnosis. During the initial visit, or from one visit to the next during the acute illness, the change in symptoms or in the physical examination over time may provide important diagnostic clues. For the child in whom a diagnosis has already been established and who does not require hospitalization, follow-up by telephone or an office visit should be used to monitor the course of the illness and to further educate and support the parents.

Chapter 50 - Injury Control

Frederick P. Rivara
David Grossman

Injuries are the most common cause of death during childhood and adolescence beyond the first few months of life and represent one of the most important causes of preventable pediatric morbidity and mortality. Advances have identified the risk factors for injuries and have developed successful programs for prevention and control. Such activities should be applied daily by the pediatrician in the office, emergency department, hospital, or community setting.

Injury Control.

The term *accident prevention* has been replaced by *injury control*. The word "accident" implies an event occurring by chance, without pattern or predictability. In fact, most injuries occur under fairly predictable circumstances to high-risk children and families. *Accident* connotes a random event that cannot be prevented. The use of the term *injury* promotes an awareness of a medical condition with defined risk and protective factors that can be used to define prevention strategies.

The reduction of morbidity and mortality from injuries can be accomplished not only through *primary* prevention (averting the event or injury in the first place) but also through s*econdary* and *tertiary* prevention. The latter two approaches include appropriate emergency medical services for injured children; regionalized trauma care for the multiply injured, severely burned, or head-injured child; and specialized pediatric rehabilitation services that attempt to return children to their prior level of functioning. This broadened scope of prevention is more properly described by the term *injury control*.

This expanded definition also encompasses intentional injuries (assaults and self-inflicted injuries). These injuries are important among adolescents and young adults and in some populations rank first or second as causes of death in these age groups. Many of the same principles of injury control can be applied to these problems; for example, limiting access to firearms may reduce both unintentional shootings as well as suicides.

Scope of the Problem

MORTALITY.

Injuries cause 45% of the deaths among 1- to 4-yr-old children and three times more deaths than the next leading cause, congenital anomalies. For the rest of childhood and adolescence up to the age of 19 yr, nearly 70% of deaths are due to injuries, more than all other causes combined. In 1999, injuries caused 17,940 deaths among individuals 19 yr and younger in the United States (Table 50–1), resulting in more years of potential life lost than any other cause.

Motor vehicle injuries lead the list of injury deaths at all ages during childhood and adolescence, even in children younger than 1 yr of age. Motor vehicle occupant injuries account for the majority of these deaths during childhood as well as in adults. During adolescence, occupant injuries are the leading cause of injury death, accounting for more than 50% of unintentional trauma mortality in this age group.

Drowning ranks second overall as a cause of unintentional trauma deaths, with peaks in the preschool and later teenage years (see Chapter 61). In some areas of the United States, drowning is the leading cause of death from trauma for preschool-aged children. The causes of drowning deaths vary with age and geographic area. In young children, bathtub and swimming pool drowning predominate, whereas in older children and adolescents, drownings occur predominantly in natural bodies of water while swimming or boating.

Fire and burn deaths account for nearly 6% of all unintentional trauma deaths and 13% in those younger than 5 yr of age (see Chapter 62). The vast majority of these (93%) are due to house fires, with most deaths caused by smoke inhalation and asphyxiation rather than severe burns. Children and the elderly are at greatest risk of these deaths because of difficulty in escaping from burning buildings.

Suffocation accounts for approximately half of all unintentional deaths in children younger than 1 yr of age. The majority of these deaths result from choking on food items such as hot dogs, candies, grapes, and nuts. Nonfood items that can cause choking include undersized infant pacifiers, small balls, and latex balloons.

Homicide is the second leading cause of injury death for infants younger than 1 yr, the second leading cause of injury death for ages 1–4 yr, and the second leading cause of injury death in adolescents (15–19 yr). Homicide in the pediatric age group falls into two patterns: "infantile" and "adolescent." Infantile homicide involves children younger than the age of 5 yr and represents child abuse (see Chapter 35). The perpetrator is usually a caretaker; death is generally the result of blunt trauma to the head and/or abdomen. In contrast, the adolescent pattern of

TABLE 50-1 -- Injury Deaths in the United States, 1999

Cause of Death	Younger than 1 yr	1–4 yr	5–9 yr	10–14 yr	15–19 yr	0–19 yr

Undetermined intent	55	43	12	37	159	306

From Web-based Injury Statistics Query and Reporting System at http://webapp.cdc.gov/sasweb/ncipc/mortrate.html

homicide involves peers and acquaintances and is due to firearms in more than 80% of cases. The majority of these deaths involve handguns. Children between these two age groups experience homicides of both types.

Suicide is rare in children younger than age 10 yr; only 1% of all suicides occur in children younger than age 15 yr. The suicide rate increases markedly after the age of 10 yr, with the result that suicide is now the third leading cause of death for 15- to 19-yr-olds, accounting for more than 100,000 potential years of life lost. Native American teenagers are at the highest risk, followed by white males; black females have the lowest rate of suicide in this age group. Approximately 60% of teenage suicides involve firearms (see Chapters 24 and 102).

NONFATAL INJURIES.

Mortality statistics reflect only a small part of the effects of childhood injuries. Twenty to 25 percent of children and adolescents receive medical care for an injury each year in hospital emergency departments, and at least an equal number are treated in physicians' offices. Of these, 2.5% require inpatient care and 55% have at least short-term temporary disability from their injuries.

The distribution of these nonfatal injuries is very different from that of fatal trauma (Fig. 50–1). Falls are the leading causes

Figure 50-1 Emergency department visit rates for leading first-listed causes of injury by age: United States, 1993–1994. (Data from Centers for Disease Control and Prevention, National Center for Health Statistics, and National Hospital Ambulatory Medical Case Survey.)

of both emergency department visits and hospitalizations. Bicycle-related trauma is the most common type of sports and recreational injury, accounting for more than 300,000 emergency department visits annually. Nonfatal injuries, such as anoxic encephalopathy from near-drowning, scarring and disfigurement from burns, and persistent neurologic deficits from head injury, may be associated with severe morbidity, leading to substantial changes in the quality of life for victims and families.

TRENDS OVER TIME.

The death rate for childhood injuries in the United States and most developed nations has declined throughout the 20th century, with substantial decreases in death rates from unintentional injuries over the past 15 yr. Homicide and suicide are the only leading causes of death in the United States to increase from 1950 to the 1990s. Suicide rates among male teens increased by 50% between 1970 and 1986, largely owing to firearm-related suicides. Since 1986, suicide rates among 15- to 19-yr-olds have decreased; rates in 1998 were 12% lower than in 1986. Homicide rates for 15- to 19-yr- old teens peaked in 1993 and fortunately have decreased by 50% since then. Both the increase and the subsequent drop in homicides were firearm related.

Principles of Injury Control.

For many years, prevention of injuries centered on attempts to pinpoint the innate characteristics of a child that result in greater frequency of injury. Most have discounted the theory of the “accident-prone child.” Although longitudinal studies have demonstrated an association between hyperactivity and impulsivity and increased rates of injuries, the sensitivity and specificity of these traits for injury are extremely low. The concept of “accident proneness” is, in fact, counterproductive in that it shifts attention away from potentially more modifiable factors, such as product design or the environment. It is more appropriate to examine the physical and social environment of children with frequent rates of injuries than to try to identify particular personality traits or temperaments, which are difficult to modify. Children at high injury risk are likely to be relatively poorly supervised, have disorganized or stressed

families, and live in hazardous environments.

Efforts to control injuries include *education or persuasion, changes in product design*, and *modification of the social and physical environment*. Efforts to persuade individuals, particularly parents, to change their behaviors have constituted the greater part of injury control efforts. Speaking with parents specifically about using child car seat restraints and bicycle helmets, installing smoke detectors, and checking the tap water temperature is likely to be more successful than well-meaning but too-general advice about supervising the child closely, being careful, and "childproofing" the home. This information should be geared to the developmental stage of the child and presented in moderate doses in the form of anticipatory guidance at well-child visits. Important topics to discuss at each developmental stage are shown in Box 50–1 .

The most successful injury prevention strategies generally are those involving changes in product design, as shown in Table 50–2 . These *passive* interventions protect all individuals in the population, regardless of cooperation or level of skill,

and are likely to be more successful than *active* measures that require repeated behavior change by the parent or child. However, for some types of injuries, effective passive interventions are not available or feasible; we must rely heavily on attempts to change the behavior of individuals. Turning down the water heater temperature, installing smoke detectors, and using child-resistant caps on medicines and household products are examples of effective product modification. Many interventions require both active and passive measures. For example, smoke detectors provide passive protection when fully functional but behavior change is required to ensure annual battery changes and proper testing.

Modification of the environment often requires greater changes than individual product modification but may be very effective in reducing injuries. Safe roadway design, decreased traffic volume and speed limits in the neighborhood, and elimination of guns from the households are examples of such interventions. Included in this concept are changes in the social environment through legislation such as laws mandating child seat restraint and seatbelt use, bicycle helmet use, and graduated motor vehicle licensing laws.

Prevention campaigns combining two or more of these approaches have been particularly effective in reducing injuries. The classic example is the combination of legislation and education to increase child seat restraint and seatbelt use; other examples are programs to promote bike helmet use among school-aged children and improvements in occupant protection in motor vehicles.

Risk Factors for Childhood Injuries.

Major factors that are associated with an increased risk of injuries to children include age, sex, race, socioeconomic status, and the environment.

AGE.

Toddlers are at greatest risk for burns, drowning, and falls. As these children acquire mobility and exploratory behavior, poisonings become a risk. Young school-aged children are at greatest risk for pedestrian injuries, bicycle-related injuries (the most serious of which usually involve motor vehicles), motor vehicle occupant injuries, burns, and drowning. During the teenage years, there is a markedly increased risk from motor vehicle occupant trauma, a continued risk from drowning and burns, and the new risk of intentional trauma. Work-related injuries associated with child labor, especially for 14- to 16-yr-olds, are an additional risk.

Injuries occurring at a particular age represent a window of vulnerability during which a child or an adolescent encounters a new task or hazard that he or she may not have the developmental skills to handle successfully. For example, toddlers do not have the judgment to know that medications can be poisonous or that some houseplants are not to be eaten; they do not understand the hazard presented by a swimming pool or an open second-story window. For young children, parents may inadvertently set up this mismatch between the skills of the child and the demands of the task. A walker converts an infant into a mobile toddler and greatly increases contact with hazards. Many parents expect young school-aged children to walk home from school, the playground, or the local candy store, tasks for which most children are not developmentally ready. Likewise, the lack of skills and experience to handle many tasks during the teenage years contributes to an increased risk of injuries,

particularly motor vehicle injuries. The high rate of motor vehicle crashes for younger teens is caused in part by inexperience but also appears to reflect their level of development and maturity. Alcohol and other drugs often add to these limitations.

Age also influences the severity of injury as well as the risk of long-term disability. For example, young school-aged children have an incompletely developed pelvis. In a motor vehicle crash, the seatbelt does not anchor onto the pelvis but rides up onto the abdomen, resulting in the risk of serious abdominal injury. Age interacts with the vehicle characteristics in that most children ride in the rear seat, which in the past was equipped only with lap belts and not lap-shoulder harnesses. Proper restraint for 4- to 8-yr-old children requires the use of booster seats. Children younger than the age of 2 yr have much poorer outcomes from closed-head injuries than do older children and adolescents.

SEX.

Beginning at 1–2 yr of age and continuing until the 7th decade of life, males have higher rates of injuries than females. During childhood this does not appear to be due to developmental differences between the sexes, differences in coordination, or differences in muscle strength. Variation in exposure to risk may account for the male predominance in some types of injuries. Although boys in all age groups have higher rates of bicycle-related injuries, adjusting for exposure reduces this excess rate. Boys may have higher rates of injuries because they use bicycles more frequently or for more hours. In contrast, sex differences in rates of pedestrian injuries do not appear to be caused by differences in the amount of walking but rather reflect differences in behavior between young girls and boys. Greater risk-taking behavior, combined with greater frequency of alcohol use, may lead to the disproportionately high rate of motor vehicle crashes among teenage males.

RACE.

African-Americans have much higher rates of injuries than whites, whereas Asians have lower rates; rates for Hispanics are intermediate between those for African-Americans and whites. Native Americans have the highest death rate from unintentional injuries. These discrepancies are even more pronounced for some injuries. The homicide rate for blacks age 15–19 yr was 63.8 per 100,000 in 1999, compared with 8.84 per 100,000 for whites. The suicide rate for Native American youth is twice the rate for whites and fourfold greater than that for Asians. The rate of

fire and burn deaths in black preschool children is more than three times higher than for whites: 5.4 per 100,000 compared with 1.5 per 100,000, respectively.

These racial disparities appear to be primarily related to poverty and educational status of parents, and the presence of hazardous environments, rather than to race. Homicide rates of blacks are nearly equivalent to whites when adjusted for socioeconomic status. It is important to understand racial disparities in injury rates but inappropriate to ascribe the etiology of these differences to race.

SOCIOECONOMIC STATUS.

Poverty is one of the most important risk factors for childhood injury. Mortality from fires, motor vehicle crashes, and drowning is two- to fourfold higher in poor children. Death rates for both African-Americans and whites have an inverse relationship with income level: The higher the income level, the lower the death rate. Native Americans have especially high rates. Other factors are single-parent families, teenage mothers, multiple providers, family stress, and multiple siblings; these are primarily a function of poverty rather than independent risk factors.

ENVIRONMENT.

Poverty increases the risk of injury to children, at least in part through its effect on the environment. Children who are poor are at increased risk of injury because they are exposed to more hazards in their living environments. For example, they may live in poor housing, which is more likely to be dilapidated and less likely to be protected by smoke detectors. The roads in their neighborhoods are more likely to be major thoroughfares. Their neighborhoods are more likely to experience higher levels of violence, and they are more likely to be victims of assault than are children and adolescents living in middle-class suburbs. The focus on the environment is also important because it directs attention away from relatively immutable factors, such as family dynamics, poverty, and race, and directs efforts toward factors that can be changed through interventions.

Motor Vehicle Injuries.

Motor vehicle injuries are the leading cause of serious and fatal injuries for individuals of all ages. Among adolescents, motor vehicle crashes alone account for 38% of *ali* deaths, including deaths from natural causes. Large and sustained reductions in motor vehicle crash injuries can be accomplished by identifiable interventions.

OCCUPANTS.

Injuries to passenger vehicle occupants are the predominant cause of motor vehicle deaths among children and adolescents, with the exception of the 5- to 9-yr group, in whom pedestrian injuries make up the largest proportion. The peak injury and death rate for both males and females in the pediatric age group occurs between 15 and 19 yr (see Table 50–1). Proper restraint use in vehicles is the single most effective method for preventing serious or fatal injury.

Much attention has been given to child occupants younger than 4 yr of age. Use of child restraint devices can be expected to reduce fatalities by 71% and the risk of serious injuries by 67% in this age group. All 50 states and the District of Columbia have laws mandating their use. Handouts given to parents by physicians emphasizing the positive benefits of child seat restraints have been successful in improving parent acceptance. Pediatricians should point out to parents that toddlers who normally ride restrained behave better during car trips than children who ride unrestrained.

Excellent films are available that discuss the advantages of child seat restraints; these can be shown to parents in waiting rooms or mothers on postpartum hospital floors. Many hospitals and communities have adopted loan programs, renting restraints at low cost. This is especially important for low-income families, who have the lowest rate of restraint use. A list of acceptable devices is available from the American Academy of Pediatrics. Children weighing less than 20?lb may use an infant seat or be placed in a “convertible” infant-toddler child restraint device. Infants younger than 1 yr or weighing less than 20?lb should be placed in the rear seat facing backward; older toddlers and children can be placed in the rear seat in a forward-facing convertible or toddler seat. Emphasis must be given to correct use of these seats, including placing the seat in the right direction, properly routing the belt, and ensuring that the child is correctly buckled into the seat. Government regulations have made the fit between car seats and the car easier, quicker, and less prone to error. Children younger than age 13 yr should never be placed in the front seat, especially if an airbag is present. Inflating airbags can be lethal to infants in rear-facing seats and to small children in the front passenger seat.

Older children are often not adequately restrained. Many children ride in the rear seat restrained with lap belts only. Unfortunately, the use of lap belts alone has been associated with a marked rise in seatbelt-related injuries, especially fractures of the lumbar spine and hollow-viscus injuries of the abdomen. These flexion-distraction injuries of the spine are usually accompanied by injuries to the abdominal organs; the presence of cutaneous seatbelt contusions in restrained children should alert the clinician to possible abdominal or spine injury. Children should use approved booster seats until large enough to comfortably wear the belt and shoulder harness alone. This occurs when the child is approximately 8 yr old and weighs 80?lb. Shoulder straps placed behind the child or under the arm do not provide adequate crash protection and may increase the risk of serious injury.

Transportation of premature infants presents special problems. The possibility of oxygen desaturation, sometimes associated

---

with bradycardia, among premature infants while in child seat restraints has led the American Academy of Pediatrics to make the following recommendations: monitoring of infants born at less than 37?wk of gestational age in the seat before discharge and the use of oxygen or alternative restraints for infants who experience desaturation or bradycardia, such as seats that can be reclined and used as a car bed. Monitoring in the neonatal intensive care unit should be done for 60–90?min.

Children riding in the back of pickup trucks are at special risk of injury, because of the possibility of ejection from the truck and serious head injury. Children traveling in the back of covered pickup trucks are at risk for carbon monoxide poisoning from faulty exhaust systems.

The rear seat is clearly much safer than the front seat for both children and adults. One study of children younger than the age of 15 yr found that the risk of injury in a crash was 70% lower for children in the rear seat compared with those sitting in the front seat. Frontal airbags appear to offer little protection to children in crashes as well as present a risk of serious or fatal injury from the airbag itself. The implementation of side airbags also poses a risk for children who are in the front seat and are, for example, leaning against the door at the time of a crash. The safest place for children is in the rear seat, properly restrained for their age and size. Educational and legislative interventions to increase the number of children traveling in the rear have been successful.

TEENAGE DRIVERS.

Drivers aged 15–17 yr have over twice the rate of collisions than motorists 18 yr of age and older. Formal driver education courses appear to be ineffective as a primary means of decreasing these collisions, and in fact can be counterproductive by allowing younger teens to drive. Risk of serious injury and mortality is directly related to the speed at the time of the crash and inversely related to the size of the vehicle. Small, fast cars greatly increase the risk of a fatal outcome in the event of a crash.

The number of passengers traveling with teen drivers influences the risk of a crash. The risk of death for 17-yr-old drivers is 50% greater driving with one passenger compared with driving alone; this risk is 2.6-fold higher with two passengers and 3-fold higher with three or more passengers. The risk is also increased if the driver is male and if the passengers are younger than age 30yr.

Teens driving at night are overrepresented in crashes and fatal crashes, with nighttime crashes accounting for over one third of teen motor vehicle fatalities. Almost 50% of the fatal crashes involving drivers younger than age 18 yr occur in the 4?hr before or after midnight. Teens are 5- to 10-fold more likely to be in a fatal crash while driving at night compared with driving during the day. The difficulty of driving at night combined with the inexperience of teen drivers appears to be a deadly combination.

Graduated licensing laws consist of a series of three steps over a period of time before a teen can get full, unrestricted driving privileges. These laws usually place initial restrictions on the number of passengers allowed in the vehicle and limit driving during late night hours. These laws can decrease fatal crashes of 16-yr-old drivers by as much as 50%. Graduated licensing laws have been adopted by many states.

Alcohol use is a major cause of motor vehicle trauma among adolescents. The combination of inexperience in driving and inexperience with alcohol is particularly dangerous. Approximately one fifth of all deaths from motor vehicle crashes in this age group are the result of alcohol intoxication, with impairment of driving seen at blood alcohol concentrations as low as 0.05?g/dL. More than one third of adolescents report riding with a driver who had been drinking. All states have adopted a zero tolerance policy to adolescent drinking while driving. All adolescent motor vehicle injury victims should have their blood alcohol concentration measured in the emergency department and be screened for chronic alcohol use with a standard test (the CAGE or the Short Michigan Alcohol Screening Test) to identify those with alcohol abuse problems. Individuals who have evidence of alcohol abuse should not leave the emergency department or hospital without plans for appropriate alcohol abuse treatment. Interventions for problem drinking can be effective in decreasing the risk of subsequent motor vehicle crashes. Even brief interventions in the emergency department using motivational interviewing can be successful in decreasing adolescent problem drinking.

Bicycle Injuries.

Each year in the United States, 250–300 children and adolescents die of injuries incurred while riding bicycles; bicycle-related injuries are one of the most common reasons that children with trauma visit emergency departments. The majority of severe and fatal bicycle injuries involve head trauma. A logical step in the prevention of these head injuries is the use of helmets. Helmets are very effective, reducing the risk of head injury by 85% and brain injury by 88%. Helmets also protect against injuries to the mid and upper face. Pediatricians can be effective advocates for the use of bicycle helmets and should incorporate this advice into their anticipatory guidance schedules for parents and children. Appropriate helmets are those with a firm polystyrene liner that fit properly on the child's head. Parents should avoid buying a larger helmet to give the child “growing room.”

Promotion of helmets can and should be extended beyond the office. Community education programs spearheaded by coalitions of physicians, educators, bicycle clubs, and community service organizations have been successful in promoting the use of bicycle helmets, resulting in helmet use rates as high as 60% with concomitant reduction in the number of head injuries. Passage of bicycle helmet laws also leads to increased helmet use.

Consideration should also be given to other types of preventive activities, although the evidence supporting their effectiveness is limited. Bicycle paths are a logical method for separating bicycles and motor vehicles. Safe bicycling training for children can be provided in the school and community.

Pedestrian Injuries.

Pedestrian injuries are one of the most common causes of traumatic death for 5- to 9-yr-old children in the United States and most industrialized countries. Although case fatality rates are less than 5%, serious nonfatal injuries constitute a much larger problem. Pedestrian injuries are the most important cause of traumatic coma in children and are a frequent cause of serious lower extremity fractures, particularly in the school-aged child.

Most injuries occur during the day, with a peak in the after-school period. Improved lighting or retroreflective clothing would, therefore, be expected to prevent few injuries. Surprisingly, approximately 30% of pedestrian injuries occur while the

individual is in a marked crosswalk, perhaps reflecting a false sense of security and decreased vigilance. The risk of pedestrian injury is greater in neighborhoods with high traffic volumes, speeds greater than approximately 25?mph, absence of play space adjacent to the home, household crowding, and low socioeconomic status.

One important risk factor for childhood pedestrian injuries is the developmental level of the child. Children younger than age 5 yr are at risk of being run over in the driveway. Few children younger than 9 or 10 yr have the developmental skills to successfully negotiate traffic 100% of the time. Young children have poor ability to judge the distance and speed of traffic and are easily distracted by playmates or other factors in the environment. Many parents are not aware of this potential mismatch between the abilities of the young school-aged child and the skills needed to cross streets safely.

Prevention of pedestrian injuries is difficult but should consist of a multifaceted approach. Education of the child in pedestrian safety should be initiated at an early age by the parents and continue into the school-age years. Younger children should be

---

taught never to cross streets when alone; older children should be taught (and practice how) to negotiate quiet streets with little traffic. Major streets should not be crossed alone until the child is 10 yr of age or older.

Pedestrian skills training should constitute part of a more comprehensive pedestrian safety program in a community. Legislation and police enforcement are important components of any campaign to reduce pedestrian injuries. Right-turn-on-red laws increase the hazard to pedestrians. In many cities, few drivers stop for pedestrians in crosswalks, a special hazard for young children. Engineering changes in roadway design are extremely important as passive prevention measures. Most important are measures to slow the speed of traffic and to route traffic away from schools and residential areas. Other modifications include one-way-street networks, proper placement of transit or school bus stops, sidewalks in urban and suburban areas, edge stripping in rural areas to delineate the edge of the road, and curb parking regulations. Comprehensive traffic “calming” schemes employing these strategies have been very successful in reducing child pedestrian injuries in Sweden, the Netherlands, Germany, and increasingly in the United States.

Fire- and Burn-Related Injuries (see Chapter 62).

Fire- and burn-related injuries are the fifth most common cause of unintentional injury death in the United States, with about 3,600 fire and burn deaths occurring each year. For both injuries and deaths, the first decade of life is the period of highest risk. The likelihood of burn injury is strongly related to low socioeconomic status, with highest rates among the poor, the less educated, and those living in mobile homes. Burns are much more frequent among males than females. Among children 10–14 yr of age with burns involving flammable substances, males are burned eight times more frequently than females.

One of the first effective interventions involved using nonflammable fabrics. Flame burns resulting from ignition of clothing were a common, serious burn injury, especially in small children. At least one third of those injuries involved infant sleepwear. Such burns averaged 30% of the body surface, requiring hospitalization for an average of 70 days. In 1967, the Federal Flammable Fabrics Act was passed, *requiring children's sleepwear to be flame retardant*. As a result of this and similar state legislation, clothing ignition burns in small children now account for only a small fraction of burns in children. Despite the withdrawal of tromethamine (*TRIS*)-containing clothing because of potential mutagenicity, federal flammability standards still apply to children's sleepwear. Parents should not circumvent these protective regulations by using cotton T-shirts for infant and child sleepwear.

Another hazard modification resulting in substantial reduction of injury involves *scald burns due to tap water*. Scalds account for 40% of the burn injuries in children requiring hospitalization, and a substantial proportion of these scald burns involve tap water. Scalds from hot liquids and foods are the most common reason for a burn admission to the hospital for children younger than age 5 yr. Avoiding the use of electric kettles or frying pans with long cords, not using baby walkers, not drinking hot tea or coffee while holding an infant, and keeping children away from pots cooking on the stove will help to prevent many of these injuries. Unlike those with flame burns, children with scalds generally do not die; however, many children have long hospitalizations, multiple surgical procedures, and severe disfigurement. The risk of full-thickness burns increases geometrically at water temperatures above 125°F. At 150°F, a full-thickness burn will be produced in adult skin in 2?sec. A simple and effective preventive maneuver is to lower the water heater temperature to 125°F (51.6°C). At this setting, dishwashers and washing machines operate effectively, but the risk of serious scald injury is greatly reduced. In many cities, the local power company will turn down the temperature without charge. In 1980, Florida became the first state requiring new water heaters to be preset at a temperature of 125°F.

Fireworks are a seasonal injury, and over 40% of those injured by fireworks are children younger than 15 yr of age. Community restrictions on certain types of fireworks and adult supervision of use of all fireworks have been effective in decreasing burns, amputations, and ocular injuries caused by these devices. Further product modification promises to decrease the hazards associated with certain easy-to-use cigarette lighters commonly found in the home.

Over 80% of all fire deaths in the United States occur in private dwellings. Of these deaths, 60% are caused by smoke asphyxiation and *not* flame burns. *Smoke detectors* are an inexpensive but effective method of preventing the majority of these deaths. Physicians can alter parental behavior and increase smoke detector use by offering information on smoke detectors in their offices.

Cigarettes are estimated to cause 45% of all fires and 22–56% of deaths from house fires. The combination of smoking and alcohol use appears to be particularly lethal. Most cigarettes made in the United States contain additives in both the paper and the tobacco that allow them to burn for as long as 28?min, even if left unattended. If *fire-safe* or *self-extinguishing cigarettes* replaced present types, nearly 2,000 deaths and more than 6,000 burns would be prevented annually.

Some burns result from fire setting by children or adolescents. In young children, this usually represents exploratory play. However, such behavior in older children and adolescents may signify a serious conduct disorder and warrants careful psychiatric and family evaluation. More than half of adolescent fire-setters will be involved in repeat incidents.

Poisoning (see Chapter 704).

Deaths by unintentional poisonings among children have decreased dramatically over the past 2 decades, particularly among children younger than 5 yr of age. In 1970, 226 poisoning deaths of children younger than age 5 yr occurred, compared with only 46 in 1999. Poisoning prevention represents the effectiveness of passive strategies—child-resistant packaging and dose limits per container. The Poison Packaging Prevention Act currently includes 28 categories of household products and drugs. This law has been remarkably effective in reducing poisoning deaths and hospitalizations. However, compliance with the law by pharmacists is only 70–75% at present, indicating that physicians should always specify on prescription pads that prescriptions be dispensed in child-resistant containers. In addition, difficulty using child-resistant containers by adults is an important cause of poisoning in young children today. A survey by the Centers for Disease Control and Prevention found that 18.5% of households in which poisoning occurred to children younger than 5 yr of age had replaced the child-resistant closure and 65% of the ones used did not work properly. Nearly 20% of ingestions occur from drugs owned by grandparents, a group that has difficulty using traditional child-resistant containers. There is a need for better child-resistant closures that do not require manual dexterity or strength greater than the capabilities of older adults.

Other poisoning interventions, such as “Mr. Yuk” stickers, are far less effective. They do not deter young children from ingesting labeled medications and may in fact be attractive to children younger than 3 yr of age. The most important feature of the Mr. Yuk sticker is the phone number of the local or regional poison control center. Parents of toddlers should also be given a bottle of syrup of ipecac to store in the medicine chest. In the case of ingestion, they should be instructed to call the regional poison control center or pediatrician before administering ipecac.

Drowning (see Chapter 61).

In 1999, 1,286 drownings, primarily associated with recreational activities, occurred in children and adolescents in the United States. In young children, drowning ranks second only to motor vehicle injury as a cause of traumatic

death. Although no precise data exist on the number of nonfatal water-related injuries, it is estimated that 140,000 occur annually from swimming activities alone. Diving headfirst into shallow water accounts for the most serious aquatic injuries because of spinal cord damage. Of the estimated 700 spinal cord injuries resulting from aquatic activities each year, the majority result in permanent paralysis.

The proportion of drowning deaths occurring in pools varies by region of the country. In Los Angeles, half of all drowning takes place in residential pools, a rate similar to that in other areas with large numbers of pools. Children younger than the age of 5 yr do not understand the consequences of falling into deep water and usually do not call for help. A majority of child victims drown during lapses in adult supervision. Clearly, the most effective way to prevent childhood pool drowning is through circumferential *fencing*. To give the greatest protection, these barriers should restrict entry to the pool from the yard and residence, use self-closing and self-latching gates, be at least 5?ft high, and have no vertical openings more than 4 inches wide. Ordinances to require appropriate fencing have been demonstrated to be effective. Many people have advocated “water-babies” and other swimming instruction for young children. The efficacy of such techniques is untested. The potential exists for both parent and child to become less vigilant around water, possibly with tragic consequences.

Among adolescents and young adults, alcohol and drug use has been found to be involved in nearly 50% of all drowning deaths. The risk of drowning while boating is increased 10- to 50-fold with alcohol intoxication, both related to the risk of falling overboard and to the increased risk of drowning if drunk while submerged. The *restriction of the sale and consumption of alcoholic beverages* in boating, pool, harbor, marina, and beach areas may combat this dangerous combination of activities. More restrictive licensing of boat owners should also be considered.

Personal flotation devices are thought to be an important device to protect children against drowning. Although the exact protective effect of personal flotation devices (PFDs) is unknown, a study by the U.S. Coast Guard showed that although only 7% of boats involved in mishaps lacked available PFDs, they accounted for 29% of boating fatalities. All children and adolescents should wear a PFD when boating in open water.

The risk of bathtub drowning is markedly increased in children with a seizure disorder, including older children and adolescents. These patients should be instructed to shower instead of using a bathtub.

Firearm Injuries.

Injuries to children and adolescents involving firearms occur in three different situations: unintentional injury, suicide attempt, and assault. In each case, the injury induced may be fatal or may result in permanent sequelae.

Unintentional firearm injuries generally occur in a family dwelling; 85% of firearm deaths occur in the home. In gunshot fatalities to children younger than 16 yr of age, poverty is more closely related to shooting deaths than is race or population density. Urban whites have the lowest death rate, rural whites are intermediate, and urban African-American children have the highest fatality rate.

Suicide is the third most common cause of trauma death in teenage males and the fourth for females. During the period from the 1950s to 1970, suicide rates for children and adolescents more than doubled; suicide rates peaked in about 1986 and have decreased since. Rates in 1999 were 13% lower than the peak in 1986.

Firearms have played an important role in this increase and are the most common means of suicide in males of all ages. The difference in the rate of suicide between males and females is related less to number of attempts than to the method. Women die less often in suicide attempts because they use less lethal means (mainly drugs) and perhaps have a lower degree of intent. The use of firearms in a suicidal act usually converts an attempt into a fatality.

Homicides are second only to motor vehicle crashes among causes of death in teenagers older than the age of 15 yr. In 1999, 2,546 children and adolescents were homicide victims; nonwhite teenagers accounted for 51.5% of the total, making homicides the most common cause of death among nonwhite teenagers. At present, 85% of homicides among males involve firearms, 75% of which are handguns.

In the United States today, there are an estimated 210 million to 220 million firearms. During the past 2 decades, over 6 million firearms were sold in the United States each year. Handguns account for approximately 20% of the firearms in use today, yet they are involved in 90% of criminal and other firearm misuse. Home ownership of guns increases the risk of adolescent suicide 10-fold and adolescent homicide 4-fold. In homes with guns, the risk to the occupants is far greater than the chance the gun will be used against an intruder; for every death occurring in self-defense, there may be 1.3 unintentional deaths, 4.6 homicides, and 37 suicides.

Handguns pose the greatest risk to children and adolescents of all firearms. Access to handguns by adolescents is surprisingly common and is not restricted to those involved in gang or criminal activity. Stricter regulation of handgun access by youth, rather than all firearms, would appear to be the most appropriate focus of efforts to reduce shooting injuries in children and adolescents.

One approach is information and education campaigns in firearm safety with a particular focus on reducing access by locking and unloading household guns. No data yet exist to support the effectiveness of such programs in decreasing the number of gunshot wounds in children. Safety education alone is also unlikely to have an effect on the use of firearms in homicides and suicides. Most homicides are between relatives or acquaintances and are acts of rage. Elimination of these weapons from the environment of children and adolescents is the key to reduction in firearm fatalities and injuries. Decreasing access to handguns would certainly not eliminate arguments, but it would decrease the likelihood of a fatal conclusion. In an assault, the chance of death is five times greater with a firearm than with a knife.

Physicians have a responsibility to counsel parents and patients about firearm ownership. This should include information informing them of the risks associated with owning a handgun, the risk of gun injury to all members of the household, and the special risks to adolescent males and teens with mental health conditions and alcoholism. Parents should be counseled that the safest approach is to remove the firearm from the household. If the family chooses to keep the gun, parents should be advised to store the gun in a locked container or with a trigger lock, with ammunition stored separately. Further educational information for pediatricians on counseling families and adolescents about guns can be obtained from the American Academy of Pediatrics.

Chapter 51 - Emergency Medical Services for Children

M. Denise Dowd
Frederick P. Rivara

Most children who require emergency medical care present to physicians' offices, clinics, and community emergency departments (EDs) and not to specialized pediatric EDs. This requires a community-based approach to emergency care of the child. Emergency medical services for children (EMS-C) is a concept that embodies a continuum of care and encompasses prevention, prehospital care and transport, ED and inpatient care, and necessary follow-up, including rehabilitation (Fig. 51–1).

The Role of the Primary Care Physician.

The primary care physician (PCP) has multiple important roles in EMS-C. As *educator*, the PCP's primary goal is prevention. By providing anticipatory guidance, the provider can help shape the attitudes, knowledge, and behaviors of parent and child with the goal of preventing acute medical events such as injury or status asthmaticus and managing them should they occur. As *triage officer*, the PCP receives calls that necessitate directing families to the appropriate site for emergency care. The PCP will frequently serve the role of *emergency care provider* and as such must be prepared (in terms of education, equipment, and policies) to deliver initial emergency care for common problems. Because the majority of children are not treated in a children's hospital ED but are treated in general community hospital EDs or urgent care centers, pediatricians should be *consultants* to these facilities and assist them in planning and delivering high-quality pediatric emergency care. Only 10% of ambulance calls are for pediatric patients; EMS providers may lack training and experience in caring for children; policies or procedures for caring for children may not exist or may be outdated. The pediatrician can be an *advocate* for integrating pediatric emergency care within the existing local EMS system.

Office Preparedness.

Providing anticipatory guidance to families regarding injury prevention, prompt recognition and treatment

Figure 51-1 The EMS-C continuum of care: Seriously ill and injured children interface with a large number of health care personnel as they move through the EMS-C system. The system both begins and ends in the community.

of illness, and accessing emergency care are important roles for the PCP. These may involve providing written materials and developmentally appropriate counseling. Parents and other adult caretakers of medically fragile children should consider learning CPR, and children can be taught to access 911. In addition to teaching the family how to prevent and manage emergencies, the PCP's office should be prepared to handle the medical emergencies that will inevitably present there.

Although the need for full CPR occurs relatively infrequently in an office setting, most practices see children in need of acute intervention or hospitalization on a regular basis. Primary care providers and their staffs may find themselves ill equipped to treat patients with impending shock, respiratory failure, or a seizure in an examination room or for patients whose condition deteriorates while waiting to be seen. Emergency preparedness in the office requires training and continuing education for staff members, policies and procedures for emergency intervention, ready availability of appropriate resuscitation equipment, knowledge of local resources for EMS response and transport, and a working relationship with area EDs to ensure that children are cared for in facilities with expertise in pediatric emergency care.

STAFF TRAINING AND CONTINUING EDUCATION.

Initial recognition by an office staff member that a child requires emergency treatment may occur in the course of a telephone call, in the waiting room, or in an examination room. All office personnel, including those seated at the front desk, must be capable of recognizing a child with altered mental status, shock, or respiratory distress/failure and must be aware of an appropriate action plan for rapid intervention.

It is a reasonable expectation that all office staff, including receptionists and medical assistants, be trained in adult and child CPR and first aid and that they maintain their certification on an annual basis. In addition to these requirements, nurses and physicians should have training in a systematic approach to pediatric medical and trauma resuscitation. Core knowledge may be obtained through standardized courses in pediatric advanced life support (ALS) offered by national medical and nursing associations. Frequent recertification is important for maintaining knowledge and skill. Examples of such curricula include the American Heart Association's Pediatric Advanced Life Support (PALS) course, the Advanced Pediatric Life Support (APLS) course sponsored by the American Academy of Pediatrics and the American College of Emergency Physicians, and the Emergency Nurses Pediatric Course (ENPC), the Neonatal Resuscitation Program (NRP), and Pediatric Emergency Nursing self-instruction manual sponsored by the Emergency Nurses Association.

POLICIES AND PROCEDURES.

Standardized protocols for telephone triage of seriously ill or injured children are essential, especially if nonphysician personnel take after-hours calls. When a child's status is in question and prehospital care is available, ambulance transport in the care of trained personnel is always preferable to transport by private car. This avoids the potentially serious medical consequences of relying on unskilled and distraught parents without the ability to provide even basic life support (BLS) measures to transport an unstable child to an ED. Written office policies and procedures for the management of status asthmaticus, upper airway obstruction, seizures, ingestions, shock, sepsis/meningitis, trauma, head injury, anaphylaxis, and cardiopulmonary arrest should be generated and made available to all potentially involved staff members.

RESUSCITATION EQUIPMENT.

Availability of necessary equipment is a vital part of an emergency response. Every physician's office should have essential resuscitation equipment and medications packaged in a pediatric resuscitation cart or kit (Table 51–1). This kit should be checked on a regular basis and kept in an accessible location known to all office staff. Outdated medications, a laryngoscope with a failed light source, or an

empty oxygen tank represents a catastrophe in a resuscitation setting; these can be easily avoided if an equipment checklist and maintenance schedule are implemented. Responsible staff should receive routinely scheduled in-service training on equipment location and use, a task that may best be accomplished by a regular schedule of “mock codes” in which all office staff participate. A pediatric kit that includes posters, laminated cards, or resuscitation tapes specifying emergency drug doses and equipment size by age, weight, or height is invaluable in avoiding critical therapeutic errors during resuscitation.

To facilitate emergency response when a child needs rapid intervention in the office, all personnel should have a preassigned role. Organizing a “code team” within the office ensures that necessary equipment is made available to the physician in charge, that an appropriate medical record detailing all interventions and the child's response is generated, and that the call for EMS response or a transport team is made in a timely fashion.

TRANSPORT.

A decision must be made on how to transport a child to a facility capable of providing definitive care once the child has been stabilized. If a child has required an artificial airway or cardiovascular support, has altered mental status,

continues to have unstable vital signs, or has significant potential to deteriorate en route, it is not appropriate to send the child via private car, regardless of proximity to a hospital. Even when an ambulance is called, it is the primary care provider's responsibility to initiate essential life support measures and attempt to stabilize the child before transport.

In metropolitan centers with numerous public and private ambulance agencies, primary care providers must be knowledgeable about the level of service that is provided by each. The availability of basic life support (BLS) versus advanced life

support (ALS) services, transport team configuration, and pediatric expertise vary markedly among agencies. It may be appropriate to consider aeromedical transport when definitive or specialized care is not available within a community or when ground transport times are prolonged. In that case, initial transport via ground to a local hospital for interval stabilization may be undertaken pending arrival of the aeromedical team. When a child is to be transported by air or ground, copies of the child's pertinent medical records as well as any radiologic studies or laboratory results should be sent with the patient (Box 51–1) and a call made to the physicians at the receiving facility to alert them to the referral and any treatments administered. Such prenotification is not merely a courtesy; direct physician-to-physician communication is essential to ensure adequate transmission of patient care information, to allow mobilization of necessary resources in the ED, and to redirect the transport if the emergency physician believes that the child would be better treated at a facility with specialized services. The referring physician is legally responsible for patient safety until the patient's care is taken over by the accepting physician.

Pediatric Prehospital Care.

Prehospital care refers to emergency assistance rendered by trained emergency medical personnel before a child reaches a treating medical facility. Although most communities in the United States have a formalized EMS system, the nature of the emergency medical response depends in part on local demographics and population base. EMS may be provided by volunteers or paid professionals. Key points to recognize in considering the interface between the community physician and the local EMS system include access to the system, provider capability, response/transport times, and destination.

ACCESS TO THE EMS SYSTEM.

Most metropolitan and many rural communities in the United States have a “911” telephone system that provides direct access to a dispatcher who coordinates police, fire, and EMS response. Some communities have an “enhanced 911” system, in which the location of the caller is automatically provided to the dispatcher, permitting emergency response even if the caller, such as a young child, cannot give an address. The extent of medical training for these dispatchers varies between communities, as do the protocols by which they assign an emergency response. In some smaller communities, no coordinated dispatch exists and emergency medical calls are handled by the local law enforcement agency.

In activating the 911 system, it is important for physicians to make it clear to the dispatcher the nature of the medical emergency and the condition of the child. In many communities,

Box 51-1. Checklist for Patient Transport

1. Obtain written consent for transfer from the patient's parent or guardian.
2. Call receiving physician and document acceptance of transfer on the appropriate form and patient's medical record, including name of accepting physician and time of acceptance.
3. Call and give report to appropriate transport agency.
4. Copy the medical record, including transport consent forms.
5. Copy all diagnostic tests, including radiograph copies.
6. Document name of transport agency and the time at which the transport occurred.

dispatchers are trained to ask a series of questions per protocol, allowing them to send out EMS personnel of an appropriate level of training.

PROVIDER CAPABILITY.

There are many levels of training for prehospital EMS providers, ranging from individuals capable of providing only first aid to those trained and licensed to provide ALS in the field. EMS personnel, whether EMT or paramedic, all receive training in pediatric emergencies; however, pediatric cases actually constitute a minority (approximately 10%) of all EMS cases.

First responders may be law enforcement officers, firefighters, or community volunteers who are dispatched to provide emergency medical assistance. They have approximately 40?hr of training in first aid and CPR. Their role is to provide rapid response and stabilization pending the arrival of more highly trained personnel. In some smaller communities, this represents the only prehospital emergency medical response available.

Emergency medical technicians (EMTs) are volunteers or paid professionals who provide the bulk of emergency medical response in the United States. Basic EMTs may staff an ambulance after undergoing an approximately 100-hr training program. They are licensed to provide BLS services but may receive further training to expand their scope of practice to intravenous catheter placement and fluid administration, endotracheal intubation, and use of an automatic external defibrillator, under the direction of a physician advisor.

Paramedics, or EMT-Ps, represent the highest level of EMT response, with medical training and supervised field experience of approximately 1,000 hours. They provide

ALS services in the prehospital setting, functioning out of an ambulance equipped as a mobile intensive care unit. Paramedic skills may include endotracheal intubation; the placement of peripheral, central, or intraosseous lines; intravenous administration of drugs; administration of nebulized aerosols; needle thoracotomy; and cardioversion/defibrillation. Paramedics work under the supervision of a physician advisor.

Aeromedical transport team configuration can vary widely and may include physicians, nurses, respiratory therapists, or paramedics. The amount of pediatric training of team members also varies, and it is important to confirm that an appropriate standard of care can be provided during interfacility transport.

The level of training of the prehospital personnel dispatched to the scene of a medical emergency depends on the condition of the patient, available resources, and local protocols. It is important to realize that attention has only recently been focused on *pediatric* prehospital care. Training and equipment for pediatric emergency care have historically been given inadequate attention in national certification curricula and by EMS agencies primarily geared toward adult patients. In some communities, the standard of pediatric prehospital care may not match that offered to adult patients in similar condition. The EMS-C initiative sponsored by the Maternal and Child Health Bureau, U.S. Department of Health and Human Services, has provided program development grants to improve pediatric emergency services in all 50 states. This has led to increased awareness of the special needs of acutely ill and injured children and to the development of many programs and products to enhance their care.

RESPONSE/TRANSPORT TIMES.

Depending on the demographics of a community, the location of the incident, and the nature of the EMS available, EMS response times after a call for assistance may range from a few minutes to longer than an hour. Unfortunately, even in communities with relatively rapid response times, individuals may be reluctant to call for help because of a misperception that the 911 system should be activated only for full resuscitations. If a child is physiologically unstable (with marked respiratory distress, cyanosis, signs of early shock, or altered mental status) or has significant potential to deteriorate en route to the ED, or if the parents' ability to comply promptly with recommendations for ED evaluation is in

question, an EMS transport should be initiated. Inherent dangers lie in the attitude that a parent can get to the hospital faster by private car.

DESTINATION.

The destination to which a pediatric patient is transported may be defined by parental preference, provider preference, or agency protocol. In communities with an organized trauma system or a system of pediatric designation based on objective capabilities of the area hospitals, seriously ill or injured children may be triaged by protocol to the highest-level center reachable within a reasonable amount of time. The Pediatric Trauma Score (PTS) or Revised Trauma Score (RTS) (see Chapter 57.8) can be used to assess the severity of injury. Children with a PTS less than 8 or an RTS less than 11 should be treated in a designated trauma center. In communities that do not have a hospital with the equipment and personnel resources to provide definitive inpatient care, interfacility transport of a child to a regional center should be undertaken after initial stabilization. The primary care provider may be involved in this decision-making process and must make a critical assessment of the local hospital's capabilities. When interfacility transport is to be undertaken, indications for transfer, parental consent for transfer, and acceptance of the patient by the receiving physician all must be clearly documented in the medical record.

The Emergency Department.

The ability of hospital emergency departments to respond to the emergency care of children varies and depends on a number of factors, including available equipment and supplies, training and experience of the staff, and availability of pediatric subspecialties. The majority of children who require emergency care are evaluated in community hospitals by physicians or other health care providers with variable degrees of pediatric training and experience. Children account for 25–30% of all ED visits, but only a fraction of them represent true emergencies. Because the volume of critical pediatric cases is low, emergency physicians and nurses working in community hospitals often have limited opportunities to reinforce their knowledge and skills in pediatric resuscitation. Pediatricians from the community may be consulted when a seriously ill or injured child presents to the ED and should have a structured approach to initial evaluation and treatment in an unstable child of any age, regardless of the underlying diagnosis. Early recognition of life-threatening abnormalities in oxygenation, ventilation, perfusion, and central nervous system (CNS) function and rapid intervention to correct those abnormalities are key to successful pediatric resuscitation.

Because not all EDs are equally capable of treating an ill or injured child, it is the responsibility of the referring physician to be aware of the pediatric capabilities of hospitals in the area. Critically ill and injured patients have an improved outcome when cared for in regional referral centers. This is particularly true for neonatal emergencies, major trauma, burns, head injuries, and specific pediatric surgical problems. Thus, although initial stabilization of these patients may take place in a local community hospital, definitive and long-term care should be delivered in major referral centers especially equipped to provide such care.

Minimal standards must be met by community emergency departments to ensure that children receive the best emergency care possible. Guidelines for care of children in the ED have been published and are endorsed by both the American Academy of Pediatrics (AAP) and the American College of Emergency Physicians (ACEP). These guidelines provide current information on policies, procedures, protocols, quality assurance methods, and equipment and supplies considered essential for managing pediatric emergencies. Specific recommendations on equipment, supplies, and medications for the ED are listed and updates are available on both the AAP and ACEP websites. A list of sample policies and protocols for EDs that care for the ill or injured child are given in Box 51–2 .

Box 51-2. Pediatric Specific Policies and Protocols for the Community Emergency Department

- Triage and initial assessment
- Child safety
- Suspected child abuse or neglect
- Family violence
- Consent for treatment
- Emancipated minors
- Sedation and analgesia
- Transfer to a higher level of pediatric care
- Telephone consultation with pediatric subspecialists
- Do not resuscitate (DNR)
- Death of a child
- Sudden infant death and apparent life-threatening event (ALTE)
- Daily verification of location and functioning of pediatric equipment and supplies
- Immunizations
- Parental presence during procedures
- Ground and air transport procedures

Although secondary to an ED staffed by individuals skilled in the emergency care of children, the environment of the ED treating children must be respectful of the needs and expectations of children and their families. A child-safe emergency department is the first priority. Wires and sharps boxes in examination rooms should be out of reach; waste containers should be covered, tall, and stable; and electrical sockets should be covered. Within practical limits the child must be separated from the frightening sights and sounds that are so common in EDs. Examples of ways to meet this goal are (1) a separate ambulance entrance, (2) resuscitation rooms that are private, (3) "quiet rooms" for upset family members, and (4) soundproof procedure rooms. Distraction and entertainment go a long way for the child and the family waiting for or undergoing treatment in an ED. Televisions with VCRs, game boards, interactive toys, and crafts can be considered essential tools of the emergency care of the child. Not only are these techniques comforting to the child and family but also helpful to the practitioner attempting to assess the child. The examination of the calm child is much more reliable than the examination of a frightened, crying child.

The way in which a family supports a child during a crisis is critical in the recovery. Surveys of parents have indicated that the majority of parents want to be with their child during invasive procedures and even resuscitation. This has been shown to reduce parental and patient anxiety and does not interfere with the procedure.

The Community

SCHOOLS.

Because children spend a great deal of time in schools, schools must be prepared to attend to emergency needs of normally healthy children as well as children with special health care needs. In 1990, as a result of passage of the Individuals with Disabilities Education Act, more chronically ill and technologically dependent children attend regular school and thus the need for preparation to deal with acute medical problems has increased. Guidelines for emergency medical care in schools have been published by the AAP and include suggested procedures, staff and staff training, documentation, and parental notification.

The range of pediatric emergencies taking place in schools is wide and includes acute emotional/behavioral events (suicide), exacerbation of chronic disease (asthma), injuries, and disclosure of child abuse. School nurses may not be available to assist in the handling of such emergencies, requiring faculty to be prepared to do so. Key factors determining a school's ability to respond to medical emergencies include comprehensive written policies for managing an emergency; basic emergency supplies kit; training of all school personnel required to respond to an emergency in CPR and basic first aid; familiarity and collaborative relationships with local EMS providers and EDs; communication with parents

and caretakers concerning the medical needs of their children; and incorporation of injury prevention and basic first aid training activities into the educational curriculum.

DISASTER PREPAREDNESS.

Natural and man-made disasters are unfortunate but not uncommon events that affect children and their families. Children's medical and emotional needs should be addressed specifically in any community's disaster plan. Child health specialists can participate in all areas of the EMS-C response to disaster, including planning, acute management, and aftermath activities. Critical elements of a comprehensive disaster

plan are guidelines for plan activation; use of space and procurement of extra supplies; security; delineation of responsibilities of key personnel; notification of key personnel; care and transfer of nondisaster patients; care of the deceased; critical incident stress debriefing measures; and plans for disaster drills. Response to threats of bioterrorism is addressed in Chapter 706 .

Legal Aspects of EMS-C.

The physician treating the child for any emergency condition must be aware of the legal aspects of providing such care. There are numerous federal, state, and local laws with which the physician should become familiar, including issues pertaining to consent, requirements of the Emergency Medical Treatment and Active Labor Act (EMTALA), Good Samaritan laws, and child protection issues.

Written policies that conform to local and state laws regarding consent to treat minors should be developed for all practice settings in which children are treated. Parental consent for medical treatment of a minor is required before treatment, however; physicians may proceed with treatment without consent in the event that a delay would endanger the well-being of the child. The definition of which emergencies fit this category varies among jurisdictions and does not merely include life- or limb-threatening events. If parents or legal guardians are not available to give consent, every attempt must be made to reach them and those attempts documented in the child's chart.

In all 50 states physicians are mandated to report suspected child abuse to the local child protection service (CPS) by state law. Penalties for failure to report vary from state to state but may involve criminal action and substantial fines. Most states provide immunity from civil or criminal litigation if the report was made in good faith. Definitions of abuse and neglect and procedures to report vary from state to state (see Chapter 35).

The Emergency Medical Treatment and Active Labor Act (EMTALA) was enacted by Congress in 1986, and its purpose is to address the concern that hospital EDs were turning away or inappropriately transferring uninsured patients (“patient dumping”). This law applies to hospitals with EDs that participate in Medicare or Medicaid and to individual physicians practicing in those hospitals. There are three requirements of EMTALA:

1. The hospital must provide an appropriate medical screening to assess if the patient has an emergency medical condition.
2. If an emergency condition exists, the patient's condition must be stabilized, or if such measures exceed the hospital's expertise, the patient must be transferred to a hospital capable of stabilization. This aspect of the law applies to any pediatrician who is on call for consultation to the ED.
3. A hospital may transfer an unstable patient only under limited circumstances. Failure to follow EMTALA requirements can result in penalties imposed by the federal authorities.

Good Samaritan laws vary from state to state and are designed to protect individuals rendering emergency assistance at the scene of an emergency. Good Samaritan laws only apply if the physician providing care did not have pre-existing duty to render care. In general these laws will not protect against acts of gross negligence. Some state laws protect only physicians who are licensed in the state where the emergency aid is given. Good Samaritan laws do not apply when giving voluntary medical assistance in air emergencies. Of related importance, medical kits aboard airplanes are not currently required to carry pediatric equipment.

Psychosocial Aspects of EMS-C.

Emergencies involving children are undoubtedly stressful for the child, the parent, and the EMS-C providers. The health care system must be responsive to the emotional and mental health needs of all involved. Parents should be given the opportunity to be with their child in the ED during procedures and even resuscitation and must be involved in decision making. The attitude of the individual communicating with families and the clarity of the information given are crucial to families, especially when the news is bad. Verbal information should be accompanied by written plans and instructions whenever possible.

Staff should be trained in appropriate coping and calming techniques for parents and for children at different developmental levels. Distraction skills, using appropriate level language to explain procedures, and methods to support children and parents should be a priority in continuing education programs for staff.

Screening for and addressing mental health needs should occur in the emergency department. Increasing evidence that post-traumatic stress disorder is both common and impacts on recovery from illness and injury necessitates that patients and families obtain appropriate follow-up services. Attention to substance abuse among adolescents presenting for care, especially with trauma, is as important as dealing with their injuries. Brief interventions in the ED using motivational interviewing can have a significant impact on problem drinking and later risk of injury.

Chapter 52 - Pediatric Critical Care: An Overview

Lorry R. Frankel

General pediatricians need to understand what constitutes intensive care and should be familiar with the evaluation and stabilization of a child who has an impending life-threatening event or who has recently had a life-threatening event. This knowledge facilitates the management and transfer of the critically ill child to an appropriate facility for care. Pediatric critical care represents a convergence of knowledge, technologies, and approaches to multisystem organ failure from the emergency department, operating room, neonatal intensive care areas, and adult intensive care units (ICUs). Before the development of specialized areas to care for critically ill or injured pediatric patients, most critically ill children were cared for in either adult intensive care or neonatal intensive care units. This resulted in placement of these children alongside geriatric or neonatal patients, whose medical, nursing, and psychosocial needs were significantly different.

Children having acute neurologic deterioration, respiratory distress, cardiovascular compromise, or life-threatening traumatic injuries constitute the most common admissions to a pediatric intensive care unit (PICU). Unlike pediatric patients who require general care, these patients usually have a disease process that affects more than one organ system, commonly referred to as multiple organ system failure (MSOF) or dysfunction (MSOD). Successful PICUs use a multidisciplinary approach to care for these patients. Staff are also trained to manage the psychosocial dynamics encountered among the patients, the parents and other family members, and the various teams of health care professionals including other subspecialists (pediatric cardiology, surgery, pulmonology, neurology) involved in the care of these patients. Communication among the individuals caring for these patients is imperative and involves periodic team conferences with the family, the primary physicians, and the various pediatric subspecialists caring for these complicated and critically ill patients. The pediatric intensivist is a board-eligible or board-certified physician with subspecialty training in the care of critically ill pediatric patients and is usually the team leader. The patient population is diverse in age and disease processes. The most active PICUs admit more than 350 patients per year, with a fairly even mix of medical and surgical diseases; the number and distribution vary with the emphasis on various programs.

Patients are admitted to a PICU because they require a very high level of monitoring of vital signs and other body functions not available in other parts of the hospital (see Chapter 55). These patients may need mechanical ventilation, invasive intravascular monitoring, and frequent attention by both the nursing and the medical staffs (Table 52–1). The children may be admitted directly from physicians' offices, clinics, the emergency department, or the operating rooms. Most PICUs have active transport programs to facilitate the transfer of critically ill children (see Chapter 53). This enables patients to be evaluated and stabilized as well as transported to the appropriate regional PICU. This extension of critical care services to the community and regional areas is essential to provide optimal care to children who have sustained a life-threatening illness or injury.

Unit Organization.

PICUs are specially designed and equipped facilities that require nurses, respiratory therapists, pharmacists, and physicians trained to care for critically ill children (see California Children's Services Standards for Pediatric Critical Care Units). The administrative structure for the ICU facilitates the multidisciplinary approach to the care of critically ill patients. It also enables the unit to establish training guidelines for the staff, evaluate equipment, review use of costly resources, and provide objective assessment of the effectiveness of new therapies. A unit director certified in pediatric critical care medicine works closely with nursing leadership and the other physicians to promote integration of critical care and the care provided by other subspecialists who practice in the unit. Assistance from anesthesia is helpful in developing clinical pathways for sedation and pain management and protocols needed to facilitate the transfer of patients from the operating room to the PICU. A surgeon with interests in trauma care is instrumental in developing the appropriate protocols required to care for injured patients. Radiology and laboratory services should be available as emergency “stat” services. Ideally, a pharmacist should be present in the PICU. The creation of a critical care committee is also helpful to formulate policies for the ICU, such as those regarding admission and discharge criteria; the role of the various attending physicians; credential criteria for physicians and physician extenders who practice in the PICU; the role of the house officers in the care of a critically ill child; transfer agreements with other hospitals to accommodate overflow patients during time of high census; and *quality assurance*.

TABLE 52-1 -- **Criteria for PICU and PIICU Admission and Discharge**

	Admission Criteria	Discharge Criteria
PICU	Patients who need *invasive monitoring:* arterial and central venous catheters, pulmonary arterial lines, ICP catheters Patients with evidence of: *Respiratory impairment or failure* *Cardiovascular compromise:* shock, hypotension, hypertensive crisis *Acute neurologic deterioration:* coma, status epilepticus, increased ICP *Acute renal failure* requiring dialysis or CVVH *Bleeding disorders* that necessitate massive transfusions	Patient may be discharged from the PICU once the disease process has reversed itself and care can be provided in a less intense environment: Patient no longer requires invasive monitoring Patient can protect his/her airway (cough and gag reflexes) Patient is hemodynamically stable
PIICU	Patients who do *not* require respiratory assistance for acute respiratory failure but may require continuous noninvasive monitoring of vital signs, BP, SaO_2 , TCO_2 $TCCO_2$ Patients who require chronic respiratory support via tracheostomies or noninvasive ventilation Patients who are in early cardiovascular failure and require monitoring of vital signs (noninvasive monitoring) Patients with acute neurologic injury but with a patent airway that they can protect themselves Patients with MSOD who do not need a PICU, but nursing care is not available elsewhere (e.g., trauma victims, DKA)	Patient may be discharged from the PIICU when it has been determined that care can be provided in general care areas

BP = blood pressure; CVVH = continuous venovenous hemofiltration; DKA = diabetic ketoacidosis; ICP = intracranial pressure; MSOD = multisystem organ dysfunction; PICU = pediatric intensive care unit; PIICU = pediatric intermediate intensive care unit; SaO_2 = arterial oxygen saturation;TCO_2 = transcutaneous oxygen;$TCCO_2$ = transcutaneous carbon dioxide.

Quality indicators may include mortality, length of ICU stays, adverse neurologic outcomes, reintubation rates for failed extubations, acquired injuries from intubations or other invasive procedures, and unanticipated ICU admissions from various areas within the hospital. Because of the many bioethical issues associated with patients with life-threatening conditions, the hospital should have an ethics committee.

Chapter 53 - Interfacility Transfer of the Critically Ill Infant and Child

Lorry R. Frankel

Specialized transport programs (interfacility transport) bring patients from community facilities to the regionalized pediatric intensive care unit (PICU). Children are usually taken to the local emergency department by the emergency medical services provider or by their parents where their condition is assessed to determine the extent of injury, severity of illness, and physiologic instability (see Chapter 51). If the local facility does not have the capabilities to provide comprehensive intensive care, the child must be transported to a PICU. If possible, the child should be stabilized in the referring hospital while awaiting the arrival of the pediatric transport team. Regional pediatric centers have a responsibility not only to transport patients as rapidly and safely as possible but also to provide community educational programs that enable the local providers of health care to develop the necessary skills required for physiologic stabilization until the transport team arrives.

The American Academy of Pediatrics, the Association of Air Medical Services, and the Federal Aviation Administration have developed recommendations for pediatric transport programs. The members of the transport team must have the cognitive and technical skills required for the needs of pediatric patients and should be supervised by an attending physician (medical control physician [MCP]) who has expertise in either pediatric emergency medicine or pediatric critical care. All transport teams should have a team leader who is able to interact with the MCP during the transport and who is also able to manage the airway, provide respiratory support, and obtain vascular access and who has basic knowledge of pediatric drug dosing and understands the basic pathophysiology of pediatric disease and the transport environment. The transport program must have a medical director who organizes the overall program and institutes a quality assurance program that reviews transports, the equipment, and the proper use of vehicles.

Dispatch Center/Transfer Center.

The regional PICU should provide phone consultation and deploy a team of specialized health care providers to assist in stabilization of patients to transport them in a safe mobile environment to the PICU. Regional centers may develop different protocols for activation of the transport or consultation requests. Some encourage direct access to the unit, some go through the emergency department,

and others prefer to use a dispatch center or transfer center to screen the calls and facilitate the coordination of a transport. Once it has been determined that an ill child must be transported to the regional center, the MCP should be consulted to provide further input into the patient's care and to determine the best team composition and vehicle required to transport the patient.

Medical Control Physician.

The MCP may have other clinical responsibilities; however, transport requests and consultations should be prioritized so that the necessary clinical information is obtained, appropriate therapeutic interventions can occur, and undue delays are avoided when transferring critically ill patients. The referring hospital provides some of the initial life-sustaining support required for these patients. It is often necessary for the MCP to provide further input into the patient's care while the patient is in the local facility. The MCP may seek additional medical or surgical consultation from other subspecialists if necessary. The MCP has the knowledge required for the stabilization of a critically ill infant or child, the transport requirements needed, the transport environment, the pertinent geography, and the interpersonal skills, which can maintain collegiality during potentially difficult and stressful times for the referring physician and facility. The MCP will assume significant responsibility for a patient who has not yet been seen.

Team Composition.

This is based on a number of factors, including the severity of a patient's illness, the distance to the referring facility, the referring facility's insistence that certain team members be present (e.g., a physician), and the ability of the team members to work together in unfamiliar surroundings. The severity of illness is assessed by the MCP from the information provided by the referring hospital. Many transports can be staffed by a nonphysician team leader with phone contact with the MCP. In addition to the team leader, a critical care nurse is helpful for nursing care, monitoring, and administration of medications. If a child requires airway and respiratory support, a respiratory therapist should be included.

Various scoring systems have been developed to predict the need for a physician during the transport. It also appears that the team member's experience and skill in caring for critically ill patients is more important than one's educational degree. These individuals receive this experience through ongoing didactic sessions, skill training in airway management and vascular access, and case review. The use of physicians as team leaders may provide for both cognitive and decision-making capabilities, but the MCP and a nonphysician team leader via phone contact can manage many situations. The evolution of advanced practice nursing has enabled transport programs to utilize these professionals as team leaders. It is mandatory that adequate training in the assessment of the critically ill child includes developing appropriate skills such as airway management and vascular access, understanding the basic pathophysiology of pediatric disease, and having knowledge of the transport environment.

Vehicle Selection.

The selection of the vehicle is made by the MCP in coordination with the referring hospital and those who will participate in the transport. Factors to consider are the severity of illness or injury, the distance to the referring hospital, travel time required, weather conditions, vehicle availability, equipment needs, and expense. *Ground ambulance* is used for the majority of transports, which are less than 100 miles. The traffic patterns must be considered in evaluating response time. The major advantages of this mode of transport are the ability to stop en route if the patient's condition worsens and further intervention is required and the ability to take a larger team with more equipment. *Fixed-wing transports* are usually used to reach infants and children who live more than 100–150 miles from the regional PICU. They may be able to fly to areas when the

weather or altitude prevents the use of a helicopter. However, the use of fixed-wing aircraft requires several ambulance transfers. In addition, flying at altitude (especially over 5,000 feet) can have serious effects on the partial pressure and volume of gases in various body cavities and closed containers. Thus, patients who have respiratory failure and who require supplemental oxygen or those with a pneumothorax or an ileus require special care to prevent further deterioration. *Helicopters* enable a more rapid response but are expensive; the greatest hazards are poor weather and landing in poorly visualized or nondesignated landing areas. Helicopters are most useful for transports within a 100- to 200-mile radius and for going directly to the site of an injury (e.g., to pick up a trauma victim).

All vehicles must have the capability of radio or telephone contact with the MCP or the base station. In addition, each vehicle must be able to provide on-board oxygen, electrical power, and suction and must have space for adequate supplies and equipment, including oxygen tanks, pharmacy packs, respiratory therapy devices, infusion pumps and solutions, stretchers or Isolettes, and monitors. Additional space may be needed for advanced technologies such as extracorporeal membrane oxygenation and inhaled nitric oxide or helium.

Communication.

This is one of the most crucial components of a regional transport system. Dealing with a critically ill or injured infant or child is an uncommon event for community physicians. Therefore, a referring physician needs to know whom, how, and when to call for assistance in the evaluation, stabilization, and transfer of a child. Telephone contact at all levels is required to ensure that physicians talk to physicians and that nurses talk to nurses. A child's condition may change rapidly; the ability to obtain information and provide advice needs to be continuing. Using a dispatch center as the patching system to the MCP and others allows the referring physician or hospital to need only one phone number and to address acute changes that require an immediate response.

The MCP is to determine if more tests should be done at the referring hospital (e.g., various imaging studies) or should various therapeutic interventions be initiated (e.g., elective intubation for progressive respiratory distress or the initiation of inotropic support for cardiovascular failure).

Once the transport team arrives at the referring facility, the team leader should reassess the patient's condition, review all of the pertinent laboratory data and medications, and discuss the situation with the parents and referring physicians. If the patient's condition has changed significantly, the team leader should contact the MCP for additional advice. All medical records including radiographs and scans should be copied to take to the accepting facility. Before departing with the child, the MCP should be consulted again and the PICU contacted to finalize preparations to receive the patient.

The referring physician should provide written documentation of the need to transfer the patient to a higher level of care than can be provided at the referring hospital. This should include a statement that the risks, benefits, and alternatives to care for a critically ill patient have been discussed with the parents and their informed consent has been obtained to have their child transferred to another hospital with PICU capacity. Medicolegal responsibility is probably shared once communication has begun. It is therefore important to document what has been recommended to the referring facility in order to better stabilize the patient.

One problem made by community facilities is transferring a critically ill child either with a team that does not have the expertise or equipment to do so or using some other system that is equally not prepared to care for the unique needs of a pediatric patient. There may be a misconception that the quicker the patient is transported the better the outcome. Unless there is a surgical emergency, it is preferred to stabilize the child and keep the patient in the referring hospital awaiting the arrival of the trained pediatric team. The regional pediatric centers have a responsibility not only to transport a patient in as rapid and safe a process as possible but also to provide educational activities for the community so that personnel can develop the necessary skills required for further stabilization until the transport team arrives.

It is also important that both the referring facility and the regional PICU have realistic expectations about the transport team's capabilities. If it is determined that a physician with significant critical care skills is required for the transport, the PICU has an obligation to provide a team leader with this skill level. The referring hospital should not delay lifesaving interventions while awaiting the arrival of the transport team (i.e., intubation of the trachea, initiation of mechanical ventilation, or pharmacologic support) especially if recommended by the MCP.

Federal legislation prohibits hospitals from refusing, limiting, or terminating patient care for financial reasons. This originates from the Consolidated Omnibus Budget Reconciliation Act (COBRA) passed in 1986 and revised in 1990. This act requires the hospital to evaluate all patients who arrive with emergent conditions and to stabilize patients before transfer. It also requires that the transferring hospital be responsible for the medical capabilities of the receiving hospital. To facilitate the transfer of critically ill pediatric patients, some regional PICUs have developed transfer agreements with referring hospitals. This ensures that the referring hospital has developed a plan as to where and how to transfer a patient. These relationships ensure that the appropriate and safe transfer of the infant or child with a life-threatening illness occurs in as smooth and safe an environment as possible.

As telecommunication systems improve, it will become possible to provide live video viewing of the patient at the referring hospital. The expansion of telemedicine will enable the MCP to work in conjunction with the referring physicians in the evaluation and stabilization of the critically ill child. This will improve outcomes because it provides the necessary critical care expertise at the bedside of the ill patient.

Chapter 54 - Effective Communication with Families in the PICU

Lawrence H. Mathers
Lorry R. Frankel

The Pediatric Patient in an Unfamiliar Environment.

It is difficult to imagine a situation producing more sadness, fright, and anger in families than a child's serious illness that requires admission to a pediatric intensive care unit (PICU). (The terms *family* and *families* are used here to include parents, grandparents, siblings, friends, and others occupying a family-like role in the life of a child.)

Young patients and their families may face potentially life-threatening illness or surgery that can result in a permanent disability or death. Families may feel a loss of ability to protect their child from danger, to provide for his or her needs, or to have final determination over which course of treatment should be undertaken. When children are confined to a hospital bed or require restraints to prevent exacerbation of injuries, the child's response is to become more agitated and to reach out to the parents for relief and reassurance. This behavior, limited visitation, and the presence of medical equipment heighten the family's feeling of loss of control and inability to help. Unfamiliar physicians and staff may intensify parental concern and distrust.

Visitation and Presence in the Child's PICU Room.

Although patients in a PICU may not be fully alert or able to interact normally with those around them, the goal of care should be to allow the maximum time for families to be with their child and to participate actively in their child's care *(family-centered care)*. Limiting the number of visitors to two at a time has traditionally been considered wise because most PICU patient areas are crowded with equipment, the child may better benefit from contact with one or two individuals rather than a large number of visitors, and large crowds may disturb other patients. Siblings and friends should be allowed to visit but must be screened to ensure that they do not have a communicable illness and are psychologically ready to visit a critically ill child. The patient's appearance and the presence of medical devices may be very frightening to a young sibling. Rules for visitation and access should be tailored to each particular situation and should always respect the principles of patient dignity and confidentiality. Visitors may be asked to leave the room during rounds, during a nursing change of shift, and when invasive procedures are performed. Similar situations applying to another patient sharing the room may require all visitors to leave. The practice of excluding families from patients' rooms during invasive procedures and even emergency resuscitations has been revisited. When families have the option of witnessing such activities, it helps them to understand and adjust to the outcome, even when the resuscitation is unsuccessful. It can be desirable for families to be present during certain procedures to provide comfort to a conscious child.

Families may wish to review their child's medical chart. This should be arranged at a time convenient when both the family and the treating physician can be present together. Such a review may provide an opportunity to answer questions and explain unfamiliar medical terminology, which can provide further family reassurance. All health care professionals caring for a patient should adopt a consistent position on sensitive issues such as witnessing procedures and reviewing the patient's chart.

Identifying Personnel and Their Roles.

Large medical centers, especially teaching hospitals, have many physicians, students, nurses, respiratory therapists, social workers, chaplains, and others involved in the care of a patient in a PICU. A single physician (usually the senior attending physician) should assume primary responsibility for communication with the family. If a fellow or other senior trainee is named to temporarily fill this role, the attending physician should reassure the family that he or she will remain fully apprised of the patient's condition and that the fellow is acting as spokesperson with the full support of the attending physician. This person should communicate at least once daily with the family and should have enough experience to place all information in a proper context and avoid hasty and incompletely supported conclusions. Nothing frightens and angers families more than to hear significantly different descriptions of their child's condition from physicians, nurses, and others who are involved in the child's care. It is also extremely helpful if early in a child's PICU course parents receive an explanation of the roles played by the different health care providers. Pamphlets containing this information are useful but cannot entirely replace a direct discussion with the family. The family should receive reassurance that health care providers in training may act independently in certain situations but are always supervised by an attending physician. Expert consultants must exercise diplomacy when they examine a patient. If significant patient information is sought by the family from a consultant, it may be best to defer providing it until the attending physician can participate in the discussion to ensure that the consultant's observations are put in proper context.

The Role of the Physician.

To benefit patients, avoid harm, maintain confidentiality, and respect the dignity of children and their families, an intensivist assumes several roles. The physician may provide information, supporting the family in making difficult decisions about continuation of support, futility of care, withdrawal of support, and organ donation.

Families vary widely on the matter of how much they wish to defer painful decisions to the "expert" treating physicians. Most physicians do not simply provide information to families and then ask them to make a decision "on their own," but instead deliver information and follow that with suggestions based on their experience and grasp of the pathophysiology of the illness affecting an individual child. Physicians may assume the role of an important partner supporting the family in making difficult decisions. Physicians can help family members' responses by the manner in which they present the medical information to them. The physician may wish to describe one or two hypothetical situations regarding the future course of an illness and attempt to reach advance agreements about which treatments will be attempted and which will not. As best as possible, the parents and child, if possible, must be asked to articulate their preferences, which, if in the best interest of the patient, must be honored. Each mode of sharing information with families has certain advantages, and an amalgam of these approaches is often used (also see Chapter 2).

Informed Consent.

The goal of informed consent is to provide patients or parents or other adults who are responsible for representing the interests of a child with a full understanding of their choices and the benefits and risks of each potential course of action (see Chapter 2). The list of procedures and treatments that require explicit consent grows yearly, and failure to obtain proper consent exposes the caregivers to legal liability. Although informed consent is required only for certain procedures and therapies, the concept should guide all interactions between the physician, the patient, and the patient's family. Caregivers should make efforts to ensure that proper communication occurs despite language barriers or differences in educational or cultural backgrounds (see Chapter 3).

Establishing a Supportive Environment and Rapport.

Many children are in the PICU for days, weeks, or even indefinitely before death eventually intervenes. Many children who have sustained very serious injuries evolve into a dependence on mechanical ventilation, assisted feeding and chronic pharmacologic therapies, and transition to the setting of a chronic care facility. Explicit guidelines for palliative care, where the focuses are on doing everything possible to reduce suffering (e.g., pain control), maintain communication wherever possible, protect the patient against fears of abandonment and rejection, protect the patient's dignity, and recognize the difficulty faced by families who must learn to accept the reality of life and death with a severely injured child (see Chapter 38). Each year, in the United States and Canada, approximately 80,000 children die of a wide variety of causes. Although many of these deaths are sudden, many other deaths occur over longer periods of time (chronic diseases, traumatic injuries) and challenge all health care providers to assist patients and their families in facing such tragic events.

Providing Health Information Consistently and Accurately.

The goal should be to speak to the family with simple honesty and compassion about the child's condition and prognosis, unless certain

circumstances would make such a frank discussion problematic (e.g., psychiatric or other serious illness in a parent). The level of the parents' understanding of medical concepts and terminology should be taken into consideration. Their emotional lability, the need for continued care for other children at home, and career and job responsibilities all guide the physician in choosing the time and circumstances in which to hold a thorough discussion with the parents (see Chapters 38 and 64).

Although informal in-depth discussions among family members and the medical team may be the forum for major decision-making, family members also need discussions to understand the relative significance of monitor readings, laboratory tests, or an examination. A *care conference* with the family and health care providers is used to exchange information and reach a consensus about children with complex problems or those who have extended PICU stays (>7–10 days). A plenary meeting may be held with representation from the various medical and ancillary services involved in a patient's care to reach conclusions and provide information to be shared with the parents and family at another meeting with the attending physician and, if feasible, the child's primary care physician. This also provides an opportunity to evaluate the parent's concerns, emotional response, and understanding. The primary care physician may be particularly helpful in assisting the family with assimilation of the information.

Uncooperative or Hostile Families.

The vast majority of families, despite the stress and anxiety provoked by their child's serious illness, want to work with the medical staff toward the goal of improving their child's health. In all but a handful of cases, an appeal to the importance of the cooperation of parents in treating the child will defuse bad feeling and hostility. However, sometimes families feel that the way to express concern and to maintain parental control over what happens to their child is to challenge the recommendations of the medical staff, resist certain suggestions, and refuse to obey visitation and other PICU regulations. The PICU staff should encourage all families to express their concerns and should indicate a willingness to understand and accommodate their positions whenever possible; extensive discussion and counseling of these families may be required.

The frustrations, sadness, and anger associated with the illness of a child can lead some family members to become suspicious, aggressive, and occasionally violent. If there is a threat of intimidation or violence against the medical staff, hospital security and the administration should be alerted that a serious conflict has occurred. In such instances, visitation privileges may be limited, allowed only when a security guard is present, and carried out in the company of an appropriate chaperone. The focus is to care for the child, and any conflicts or animosity between family and hospital must not be allowed to detract from that effort.

Communication Regarding End-of-Life Decisions.

When a child's condition irreversibly deteriorates and death is a likely event, health care staff must discuss the possibility of limiting or terminating support. If the

possibility of tissue or organ donation exists, then discussions regarding limitation of support must be tailored to that purpose, but in many cases the gravely ill child and his or her family are the sole focus of discussions. Families must be made to feel that their contribution to such a dialogue is valuable and welcome because principles of family-centered care still apply, but at the same time family members should not be made to believe that a decision regarding their child's fate lies solely in their hands. A physician should carefully and thoroughly explain the medical facts and should be prepared to make suggestions about what would be a wise decision. In many cases families badly need to identify a physician whom they can trust, and from whom they will seek not only information but also advice on a very personal level. A family's support network, including extended family, friends, and faith community, should be recognized as valid participants in end-of-life discussions. Some families may feel poorly informed and excluded from the decision-making process, whereas others may have a positive experience. PICU staff, who are by their nature numerous and frequently moving on and off of the treating team for a given patient, should realize the special need for continuity and consistency in communications with families. Even when death is the tragic outcome of a child's hospitalization, the PICU staff can be a source of strength and compassion and may help families to know that in his or her final days a child will be treated with intelligence, respect, and genuine concern and that the need to recognize and respond to the family's shock and pain was equally important (see also Chapter 38).

Chapter 55 - Monitoring Techniques for the Critically Ill Infant and Child

Lorry R. Frankel

Monitoring critically ill patients obtains biologic-physiologic data by invasive or noninvasive techniques. Noninvasive monitoring can involve continuous evaluation of heart rate and rhythm and respiratory rate, whereas noncontinuous monitoring measures blood pressure and various laboratory values, such as blood gases. Hemodynamic and respiratory monitoring involves the placement of invasive catheters to continuously determine blood pressure and central venous pressure (CVP) and to obtain intermittent arterial blood gas values. Invasive monitoring requires special expertise in the insertion of catheters and nursing care in their maintenance and has potential serious complications (e.g., infections, thrombosis, bleeding). Noninvasive monitoring devices also enable critically ill patients to be monitored on a continuous basis with fewer complications, allowing for greater patient comfort at a reduced expense. Invasive monitoring is widely used particularly in unstable critically ill patients; however, routine bedside monitoring may also incorporate noninvasive devices that allow for continuous and real-time measurements of physiologic data. This combination complements each other and enables the clinician to have a better awareness of minute-to-minute changes.

Monitoring requirements can be divided into hemodynamic, pulmonary, and neurologic; these can be subdivided into invasive and noninvasive (Table 55–1). Both noninvasive and

TABLE 55-1 -- Monitoring Devices Commonly Used in the PICU

Monitoring Devices	Sites	Measured Variables	Limitations/Concerns
Noninvasive Monitoring			
Cardiorespiratory	Chest leads	Heart rate, rhythm, respiratory rate	Only lead II recording, difficulty with dysrhythmia recognition
Pulse oximetry	Digits, palms, ear lobe	Continuous SaO_2	Patient must be well perfused; abnormalhemoglobins and nail polish may affect results
Transcutaneous oxygen and Carbon dioxide	Usually chest wall	O_2 and CO_2	Surface electrodes warm skin to 43°C, can cause thermal injury, must be changed every 3–4?hr, useful in young infants
Capnography	End of the endotracheal tube	End-tidal CO_2 using breath-by-breath analysis	Capnographic trace is important to determine actual measurement; it is a true end-tidal representation of alveolar CO_2
Blood pressure	Upper arm, thigh, or calf	Cuff that allows for periodic cycling q 1–15?min	Similar to cuff pressure. Important to have appropriate cuff size
Electroencephalogram	Scalp surface	Provides for continuous monitoring of cranial electrical activity	Requires a specialized technician to place the electrodes and special training in interpreting the waveforms
Invasive Monitoring Techniques			
Arterial	Radial, dorsalis pedis, posterior tibial, femoral, axillary (rarely brachial)	Continuous determination of blood pressure; ability to measure blood gases and other laboratory tests	Expertise in placement and monitoring needed; may require cutdown technique; may lose distal perfusion
Central venous access for pressure measurement (CVP) and infusion	Femoral, subclavian, internal or external jugular, antecubital, or advanced from the saphenous	Allows for CVP determinations and administration of vasoactive agents and hypertonic solutions (TPN)	Requires expertise in placement, especially in very young patients; attempt to use multilumen catheters; need chest x-ray film to determine placement

Pulmonary artery catheter Swan-Ganz (balloon) catheter	Place through a sheath in the internal or external jugular, femoral, or subclavian	Allows for measurements of cardiac output, SVO2, pulmonary artery pressure; can calculate SVR and PVR	Less commonly used in pediatrics; may assist in titration of inotropic support, vasodilators, adjustment of PEEP
ICP	Skull, either with a subdural bolt, an epidural fiberoptic device, or an IVC	Measures ICP when CNS pathology is associated with cerebral edema (e.g., head injury, Reye's syndrome, or those with unexplained GCS <8)	Requires a neurosurgeon to insert the device; may be done at the bedside; increased risk of infection after 5 days; IVC can be used to remove fluid
Jugular bulb catheter	Internal jugular and threaded to the jugular bulb	Measures SVO_2 at the jugular bulb. Cerebral oxygen extraction can be calculated	Technically difficult to insert; requires training in the utility of the device and the values obtained; may allow modification of therapy

CNS = central nervous system; CVP = central venous pressure; GCS = Glasgow Coma Scale; ICP = intracranial pressure; IVC = intraventricular catheter; PEEP = positive end-expiratory pressure; PVR = pulmonary vascular resistance; SaO_2 = arterial oxygen saturation; SvO_2 = venous oxygen saturation; SVR = systemic vascular resistance;TPN = total parenteral nutrition.

invasive monitors must use age- and disease-specific criteria for setting monitor alarms because normal values for heart rate, blood pressure, and respiratory rate vary with a child's age, whereas acceptable oxygen saturations will vary with different cyanotic congenital heart lesions.

Hemodynamic Monitoring.

This is indicated in any patient admitted to the pediatric intensive care unit (PICU) who is in shock, has respiratory failure, or has sustained an acute neurologic insult. Included in hemodynamic monitoring are heart rate and blood pressure as well as CVP and pulmonary capillary wedge pressure (PCWP) and, occasionally in postoperative cardiovascular patients, right atrial and left atrial pressures (RA and LA lines). Heart rate can be measured with conventional electrodes placed on the chest, which can also provide rhythm strips usually in lead II. The lead can be changed if indicated to evaluate for other dysrhythmias, but it should not substitute for a 12-lead electrocardiogram (ECG).

Blood pressure is determined invasively and noninvasively. The choice is determined by the instability of the patient, skill levels of the physicians, and ability of the staff to maintain such devices. Noninvasive blood pressure monitoring provides for manual or automatic repeated but intermittent readings of blood pressure. Whether one chooses a conventional sphygmomanometer or an ultrasonic/Doppler device, appropriate cuff sizes are required to obtain an accurate blood pressure. The cuff should encompass approximately two thirds of the length of the part of the extremity from which it is measuring. The upper arm, lower leg, and upper leg offer the best sites for obtaining noninvasive blood pressures. Besides the cuff size, factors that affect peripheral blood flow or pulmonary vascular resistance or produce significant peripheral edema may result in abnormal values for noninvasively measured blood pressure.

Because of the technical limitations of noninvasive monitoring, invasive hemodynamic monitoring may be preferred. Sites commonly used to place catheters in an artery for invasive monitoring include the radial, u1nar, posterior tibial, and dorsalis pedis arteries. Less frequently used are the femoral, axillary and brachial arteries and, when available, the umbilical artery. Arterial lines may be inserted either percutaneously or via cutdown if one is unsuccessful with percutaneous attempts. Before attempting to insert an arterial line one should ensure that collateral circulation exists if possible by performing an Allen test (for radial or ulnar lines). Once the catheter is properly inserted, a pressure transducer and pressure tubing are used to connect the catheter to the monitor. A continuous pressure waveform tracing can then be displayed on the monitor screen and should be displayed along with the simultaneous ECG tracing. The arterial waveform may be helpful in diagnosing hypovolemia (very narrowed and blunted dicrotic notch), determining the severity of cardiac dysrhythmias (pulsus alternans), and evaluating the effects of respirations (air trapping) or high pericardial pressure on blood pressure (pulsus paradoxus). Arterial lines also allow for the frequent sampling of blood for various laboratory tests including arterial blood gases, electrolytes, coagulation panels, and others as needed.

Complications from arterial catheterization are rare but may be very serious and require aggressive therapies. Bleeding and infection are relatively rare. Usually, direct pressure to the insertion site will reduce any further bleeding. Cutdowns may require resuturing or placing topical clotting material in the incision. Colonization around the insertion site may produce bacteremia and septicemia. The most serious complication is arterial thrombosis. This is seen in patients with low cardiac output states (shock), in those where heparin was not used in the flush solution, or in those patients who have required prolonged duration of catheter placement. Thrombosis necessitates the immediate removal of the catheter. The use of intravenous heparin or thrombolytic therapy or topical nitroglycerin paste is indicated if the extremity continues to have evidence of poor perfusion. Other complications include vascular spasm, cutaneous mottling, arterial tears, pseudoaneurysms, peripheral nerve damage, and arteriovenous fistula formation. Temporal artery sites are associated with retrograde flow into the carotid artery resulting in cerebrovascular accidents and therefore should be avoided. Decreased flow distal to an extremity site may result in serious necrosis of an extremity. Excellent nursing care is required to evaluate patients on a frequent and regular basis to monitor for complications. Patients with arterial lines may have excessive blood tests; in small infants this may contribute to the development of anemia.

A *central venous catheter* (CVC) is required to care for many critically ill patients. A

CVC provides important information regarding volume status (CVP), but it also permits the safe infusion of hypertonic solutions (parenteral nutrition, bicarbonate, calcium chloride, glucose) and vasoactive agents (epinephrine, norepinephrine, dopamine) that can produce severe peripheral soft tissue damage if they extravasate from peripheral lines into the local tissues. Rapid infusions of large volumes of fluids or blood products are also possible.

CVCs may be inserted from different sites; the catheter is advanced into the thoracic cavity with the tip in the inferior or superior vena cava. Sites include the femoral, subclavian, external jugular, internal jugular, antecubital, and, rarely, saphenous veins. These catheters may be inserted percutaneously or via cutdown and tunneled under the skin to reduce the risk of infection. Catheter sizes vary with the size and age of the patient. Ideally, one should attempt to insert a multilumen catheter because this provides multiple ports for the various infusions required to care for the patient. Before the procedure the patient should have ECG leads placed so that heart rate is monitored during the procedure to detect for any dysrhythmias from inadvertent intracardiac placement. The line should terminate at the atriocaval junction to minimize cardiac perforation and tamponade. An x-ray film ensures that the catheter is in proper position. The catheter is connected via a transducer to the monitor to enable one to evaluate the waveform and obtain a CVP. A true CVP waveform contains characteristic a, c, and v waves. The presence of these waves ensures appropriate placement in the thoracic cavity but not necessarily in the appropriate location, and therefore a chest x-ray film is required. Rarely, an intravenous dye contrast study or fluoroscopy may be needed to confirm placement, because some catheters are not radiopaque. Ultrasonic guided central venous catheterization, via images or sound (Doppler for arteries), is helpful in difficult situations.

Immediate complications of CVC include dysrhythmias, pneumothorax, hydrothorax, hemothorax, air embolism, shearing of the vessel, intravascular loss of the guide wire, bleeding, apnea, oversedation, or airway obstruction. The patient should be monitored for any of these early complications. Infection usually occurs later and is associated with longer duration of catheter placement as well as percutaneous versus tunneled catheters. Thrombosis is a concern because of the duration of the catheters and the potential for associated pulmonary embolic events. The most serious and life-threatening acute or delayed complication is cardiac tamponade. This is usually the result of an intra-atrial catheter. This problem must be immediately recognized and aggressively treated.

Pulmonary artery catheters (PACs) monitor the patient's hemodynamic status when the right- and left-sided circulation's filling pressures may vary. This is common in adults after a myocardial infarction in which the left ventricle is more severely affected than the right, resulting in ventricular discordance. PACs allow one to monitor a number of hemodynamic parameters if a balloon thermodilution catheter is used (Fig. 55–1). One can measure core temperature, CVP as well as pulmonary artery pressures (PAP) and pulmonary artery occlusion pressure (PAOP), cardiac outputs, and mixed venous oxygen saturation and calculate both systemic and pulmonary vascular resistances, oxygen delivery, stroke volume, arteriovenous oxygen content differences, oxygen extraction ratios, and shunt fractions.

PACs are rarely used in pediatric patients. The most common indications are for cardiogenic shock, for severe distributive shock, for the use of very high ventilator pressures to achieve adequate oxygenation, allowing one to modulate therapy in patients with severe pulmonary hypertension, and for the perioperative management of patients who have undergone complex cardiac or other major surgeries. The limitations to the use of these catheters are predominantly patient size and unfamiliarity with these catheters. The smallest thermodilution catheter is 5 Fr, although a single-lumen 4-Fr catheter exists and is useful for measuring PAP or obtaining MvO_2 . The single-lumen catheter does not permit one to measure or calculate the data that can be obtained from the larger catheters. The balloon catheters are able to “float” into the pulmonary artery and wedge into a distal position. This provides the pulmonary artery occlusion pressure (PAOP) or pulmonary capillary wedge pressure (PCWP), which is usually reflective of the left ventricle end-diastolic filling pressure. Once this number is determined, the balloon is deflated and allowed to remain in the pulmonary artery. This minimizes potential complications of pulmonary artery erosion or infarction. Other complications include dysrhythmias, damage to the pulmonic valve, coiling in the right ventricle, balloon rupture, and infection. When these complications occur, the PA catheter must be removed.

Pulmonary Monitoring.

The monitoring requirements for patients who require significant respiratory support include blood gas determination, either from arterial or, less frequently, capillary and venous blood gases. Arterial blood gas sampling requires special technique similar to inserting an arterial line. Capillary gases usually involve the use of the infant's heel. It must be warmed to “arterialize” the blood. In the laboratory a blood gas analyzer measures the partial pressures of oxygen and carbon dioxide and the pH; the bicarbonate is usually calculated from the pH and P_{CO_2} . The pH and Pa_{CO_2} from a capillary or venous sample should closely resemble the arterial blood gas sample. However, the capillary P_{O_2} does not correlate well with the Pa_{O_2} ; and in circumstances in which peripheral blood flow is adversely affected all other parameters obtained from capillary blood gases may not correlate. Capillary and venous blood gas sampling have significant limitations.

Intermittent blood gas sampling is labor intensive and expensive. It does provide the most reliable assessment of acid-base and ventilation-oxygenation status in the critically ill patient. When the patient's clinical status requires both continuous blood pressure monitoring and frequent assessments of respiratory status, an indwelling arterial line is indicated. Devices can provide continuous pH, Pa_{CO_2} , and Pa_{O_2} when the monitoring catheter is placed in an artery; blood flows from the catheter into a closed-loop system passing the blood gas electrodes. The data are obtained in a continuous manner or intermittently. These

Figure 55-1 Components and functional features of a thermodilution flow-directed balloon flotation pulmonary artery catheter (PAC). The flexible multilumen catheter with the balloon at the distal tip inflated is in the wedge position. The proximal ends of the five lumens are labeled. The distal port is connected to a pressure measurement system for catheter insertion and subsequent monitoring. When the distal tip is within the central venous circulation, the balloon is inflated to enhance flow-direction of the tip through the right atrium into the right ventricle and then to the pulmonary

artery. Recorded pressures in the lower part of the figure correspond to these locations, confirming the course of the catheter. The last tracing on the right is that corresponding to the “wedge” position, commonly reflecting the pressure transmitted from the left atrium via the pulmonary veins and fiberoptic monitor available on adult-sized catheters. (Redrawn from Daily EK, Tilkian AG: Hemodynamic monitoring. In Tilkian AG, Daily EK [editors]: *Cardiovascular Procedures, Diagnostic Techniques and Therapeutic Procedures*. St. Louis, CV Mosby, 1986.

devices are expensive and require blood vessels of sufficient size to permit the insertion of a large catheter (at least 20 gauge). These devices are useful when placed in central venous lines and used in conjunction with pulse oximetry; this combination demonstrates good correlation of venous pH, with arterial pH and venous P_{co_2} with arterial Pa_{co_2} .

Point of care testing in the PICU and neonatal ICU (NICU) is more expensive yet more expedient and provides valuable information in minutes and at the bedside. Point of care testing may be accomplished with a handheld device that is also useful in the transport environment, in areas where the patient is not in the PICU but must have blood gas analysis performed, such as radiographic imaging suites, or when the patient's condition is so unstable that an instantaneous analysis is required. These simple devices may perform a number of other analyses, such as measuring serum electrolytes, glucose, creatinine, urea, ionized calcium, and hematocrit.

A variety of noninvasive devices and monitors have improved the care of critically ill children. *Transcutaneous instruments* permit the simultaneous determination of transcutaneous carbon dioxide tension (Tc_{co_2}) and transcutaneous oxygen tension (Tc_{o_2}). Bicarbonate levels or pH cannot be measured by transcutaneous monitoring. Other limitations include skin thickness; transcutaneous monitoring is limited to smaller infants. Transcutaneous electrodes must be warmed to 43℃, which may cause burns; they must be changed every 3–4?hr. The electrodes take 20?min to calibrate; this must be done every 4?hr. Thus, there may be various delays in obtaining important blood gas information. The major strength of transcutaneous monitoring is the ability to continuously follow Pa_{co_2} , permitting more rapid ventilator adjustments and facilitating weaning as well as reducing the costs associated with blood gas analysis.

End-tidal CO_2 (Et_{co_2}) analysis *(capnography)* measures the P_{co_2} in the exhaled gas. This technique is used in patients who are intubated and have minimal lung disease without significant intrapulmonary shunting. Capnography is based on the principle that the highest concentration of CO_2 sampled in the respiratory circuit represents the alveolar CO_2 concentration, which should also be close to the arterial (Pa_{co_2}) concentration. Gas is constantly monitored from a side port to the connector from the ventilator to the endotracheal tube. A small amount of gas is diverted from the respiratory circuit and analyzed in a spectrophotometer for P_{co_2} determination. The removal of small amounts of respiratory gas must be accounted for when calculating delivered and exhaled tidal volumes.

When interpreting $EtCO_2$ results, one needs to evaluate the graphic picture of the exhalation capnographic image to ensure that the alveolar plateau and peak are achieved. Patients who have significant intrapulmonary shunts or are spontaneously breathing may not produce an acceptable capnographic trace, and thus invalidate end-tidal CO_2 monitoring. This device permits trending and the potential for weaning of patients from mechanical ventilation; it does not replace blood gas analysis.

Capnography can also determine if one has intubated the trachea and is useful in emergent intubations. Using an analyzer that changes color on exposure to levels of CO_2 enables one to differentiate between an esophageal and tracheal intubation. The CO_2 concentration in the stomach is very low, approaching atmospheric levels of close to zero, whereas that in the lungs is markedly higher. With cardiopulmonary arrest and absent pulmonary blood flow, Et_{co_2} will also be undetectable. Indeed, successful reestablishment of the circulation can also be assessed by an elevation of Et_{co_2} .

Pulse oximetry is the standard for noninvasive bedside oxygenation monitoring. Pulse oximetry can be used in patients of all ages and does not usually cause tissue damage. Its accuracy is dependent on adequate tissue perfusion; its utility is limited in patients with significant vasoconstriction and poor peripheral perfusion. Pulse oximetry measures oxygen saturation, not the partial pressure of a gas. This is important in interpreting the significance of the value obtained. Normally, arterial oxygen saturation is 95% or more (except in patients with cyanotic congenital heart lesions). Although pulse oximetry does not provide PaO_2 , it provides just as good if not better information regarding real-time oxygen saturation. It permits the rapid assessment of oxygenation of a critically ill patient. It requires little, if any, warm-up time and is extremely portable, enabling one to assess oxygenation of patients not only in the PICU but also during transport (see Chapter 53), during procedures that require conscious sedation, and in various non-ICU settings, such as the emergency department or office. The information is extremely reliable and relatively inexpensive compared with blood gas analysis. Pulse oximetry does not provide direct measurements of carbon dioxide tension, acid-base status, or bicarbonate levels.

Neurophysiologic Monitoring.

Neurologic monitoring involves careful clinical observation accompanied by highly technical noninvasive devices (e.g., electroencephalography, evoked potentials, near infra-red spectroscopy), or invasive catheters placed to monitor intracranial pressure (ICP).

Acute neurologic deterioration represents a significant number of admissions to a PICU. Trauma, tumors, infections, seizures, vascular malformation, strokes, hypoxia, or various metabolic disorders may produce serious neurologic injury. An experienced PICU nurse should be able to perform careful serial clinical neurologic examinations. These frequent examinations evaluate the cranial nerves, especially the pupillary reflexes, and score a modified Glasgow Coma Scale (GCS) for infants and children. The GCS provides a method to quantitate the patient's level of consciousness and ability to respond to painful stimuli in an easy and standard format (see Chapter 57.1). The scores range from 3–15. Most patients with score less than 12 should be observed in the PICU until they are stable enough to be cared for in less intensely monitored areas.

Advanced techniques in the computerization of electrophysiologic monitoring enable monitoring of the brain's electrical activity through *continuous electroencephalograms (EEGs)*. Managing a child with severe status epilepticus helps determine if anticonvulsant drugs are affecting both the electrical as well as the clinical seizure activity. Patients who have refractory seizures may require a barbiturate coma; monitoring their EEG activity facilitates the suppression of seizure activity. Clinical examinations are not useful in patients requiring paralytic agents or heavy sedation; the ability to monitor seizures through continuous EEGs is essential. When interpreting the data one must be aware that artifacts can be produced from the various monitors, ventilators, or other electrical equipment commonly found in the ICU setting. Video-EEG permits one to record both the electrical changes associated with a seizure and correlate it with a clinical picture.

Evoked potentials enable evaluation of a variety of sensory pathways that include visual evoked responses (VEPs), brain-stem auditory evoked potentials (BSAEPs), and somatosensory evoked potentials (SSEPs). These are not affected by the sedative medications, which may produce an isoelectric EEG. The brainstem and somatosensory tests are the most commonly performed evoked potential studies. They may serve as an aid in providing prognostic information. Their utility in diagnosing brain death is not well recognized.

The *Bispectral Index* (BIS) can be used to monitor the neurologic status of both sedated and unsedated critically ill patients. BIS is a statistically derived variable that provides information about the interaction of brain cortical and subcortical regions. The BIS score ranges from 0–100 and is a reliable index of the state of consciousness in normal subjects. Scores more than 95 indicate full consciousness. Of sedated patients, 95% are unconscious if the BIS score is 50. BIS correlates with the depth of sedation of patients who require mechanical ventilation and sedation after surgery or medical illness. BIS has been proposed as a guide to prevent oversedation in the critically ill. Unfortunately, the BIS score may be complicated if the EEG also reflects changes in the neurologic status of the patient that are caused by the illness itself.

Radionuclide imaging is rarely performed in the PICU; it may provide some useful information regarding cerebral blood flow. A portable gamma camera allows tests to be performed at the bedside. Cerebral blood flow studies allow one to confirm brain death if there is equivocation. It also permits one to quantify cerebral blood flow to injured areas of brain. The clinical significance of this is unclear.

Invasive neurologic monitoring involves ICP monitoring and jugular bulb catheterization. The indication for ICP monitoring includes any acute neurologic deterioration where elevated ICP may produce further injury to the patient. Usually, acute traumatic events with a GCS less than 8 will require a monitoring device inserted either in the operating room or at the bedside in the PICU. The type of device and how it is inserted is usually the responsibility of the neurosurgeon placing the device (Fig. 55–2). Ventriculostomy as well as intraparenchymal, subdural, or subarchnoid placement of catheters can be used. All but the intraparenchymal catheters are connected to the transducer via a fluid-filled tubing device. The ventriculostomy and the intraparenchymal fiberoptic devices are the most reliable and most used devices for monitoring ICP. A ventricular catheter allows one to not only measure ICP but also remove fluid if necessary, thereby providing a therapeutic option. The intraparenchymal fiberoptic system provides for a very reliable method of ICP measurements, but does not permit the removal of cerebrospinal fluid (CSF). It is not a fluid-filled system but is easy to use.

The device is connected to a transducer and then to the monitor. A waveform with a numeric value is produced. The ICP should be less than 20?cm H_2O. When monitoring ICP, it is imperative that the systemic arterial blood pressure be determined simultaneously. The difference between the mean arterial pressure and the ICP is the cerebral perfusion pressure. This should be more than 50?in older patients and slightly less in younger children. The complications associated with ICP monitoring include bleeding (check coagulation factors before insertion), infection if left in for more than 5 days, injury to the brain parenchyma (usually only intraventricular catheters), and CSF leak.

Jugular bulb monitoring enables one to obtain continuous oxygen saturation (JSa_{O_2}) measurements using an indwelling fiberoptic catheter placed in the jugular vein and advanced cephalad to the level of the jugular bulb. The values obtained correlate with the jugular Pa_{O_2} content and do not require blood sampling for actual determination of the oxygen saturations. The jugular bulb is located at the base of the skull and just outside the jugular foramen. It is the point of exit of the blood draining most of the cerebral hemispheres. The clinician is

Figure 55-2 Sites for monitoring intracranial pressure. A variety of monitor types are shown. Intraventricular catheters are most often fluid-filled tubes connected by pressure tubing to a pressure transducer. CSF can be withdrawn through the catheter. Subarachnoid (also subdural) monitors are fluid-filled, hollow devices that can be bolted to the calvaria connected by pressure tubing to a pressure transducer. CSF cannot be withdrawn. Epidural monitors are waferlike devices of several types, placed in the epidural space. CSF cannot be withdrawn. Intraparenchymal pressure, without the ability to withdraw CSF, can also be monitored. (Redrawn from Lyons MK, Meyer FB: Cerebrospinal fluid physiology and the management of increased intracranial pressure. *Mayo Clin Proc* 1990; 65:684.)

provided with information that enables one to determine how well the injured brain is utilizing oxygen. By knowing the saturations of oxygen in both the systemic arterial and jugular vein, one is able to calculate the arteriojugular difference for oxygen (AJD_{O_2}). This is normally 4–9?mg/dL. Levels below this indicate cerebral hyperemia, and the clinician may select therapies designed to decrease cerebral blood flow. Levels greater than 10?mg/dL may indicate ischemia and necessitate further tests to determine the extent of the brain injury. It is hoped that using the values obtained from ICP, AJD_{O_2}, and cerebral blood flow, one may alter therapy to improve outcome.

Chapter 56 - Scoring Systems and Predictors of Mortality

Joseph V. DiCarlo
Lorry R. Frankel

Scoring systems are useful for making triage decisions and assessing the performance of an intensive care unit, but they are of limited use in predicting prognosis in individual cases. Various scoring systems are currently used in the pediatric intensive care unit (PICU): (1) *organ specific*, such as the Glasgow Coma Scale (see Chapter 57.7 and Table 57–3) or the croup score (see Chapter 371), (2) *mechanism of injury*, such as the Pediatric Trauma Score (see Table 57–18) or Injury Severity Score, and (3) *pediatric*, such as the Pediatric Index of Mortality (PIM), the Physiologic Stability Index (PSI), or the Pediatric Risk of Mortality (PRISM).

Pediatric Risk of Mortality.

This system, a revision of the PSI, assesses the severity of illness in a population of pediatric patients. The PRISM in its third version (PRISM III) is used to compare and evaluate the performance and resource use among various PICUs. It is based on 17 physiologic variables subdivided into 26 ranges (Fig. 56–1). A patient's past medical history is also taken into account, particularly chronic illness and previous PICU days. The PRISM score has a consistently strong relationship between the number of malfunctioning organ systems at 12 and 24?hr and the mortality risk in a given PICU. Attempts to use PRISM for decision making in a single patient are not valid, owing to less than “adequate certainty.” The PRISM is most useful in assessing case mix adjustments between units and the overall outcomes for a population of patients in a PICU. A PICU that performs a periodic self-assessment using PRISM can determine if its performance is on a par with a reference population. If performance is below standard, a chart review may reveal the reasons, such as high secondary infection rates, comorbidity issues, and decisions to withdraw or limit therapy. Changes in the score over time may document improvement or deterioration. PRISM is also useful in research in ensuring that control and experimental groups are similar.

Pediatric Trauma Score (see Table 57–18).

This score takes into account a child's size, the accessibility of the airway, the systolic blood pressure, the level of consciousness, and the presence or absence of wounds and fractures. Below a certain cutoff, transfer to a dedicated trauma center is recommended (see Chapter 57).

Other Physiologic Scoring Systems.

Other scoring systems are less useful in pediatrics. The Acute Physiology and Chronic Health Evaluation (APACHE) system is used in adult intensive care units. The PRISM III is better suited to the physiology of a child. The PSI is a refinement of APACHE that attempts to make age-related adjustments. The Therapeutic Intervention Scoring System (TISS) relies on the type and amount of therapy given and therefore may indirectly reflect severity of illness and directly reflect resource utilization. A single calculation, the Oxygenation Index [OI = (F_{IO_2} mean airway pressure)/Pa_{O_2}] is predictive of survival in many forms of respiratory failure.

Novel Therapies and Refinement of Practice.

Intensivists attempt to improve survival by employing new treatments such as

Figure 56-1 The Pediatric Risk of Mortality III (PRISM III) Score. Numbers in parentheses refer to *Notes*. *CV*, cardiovascular; *PICU*, pediatric intensive care unit; *ICU*, intensive care unit; *CPR*, cardiopulmonary resuscitation; *DKA*, diabetic ketoacidosis; *CNS*, central nervous system; *GCS*, Glasgow Coma Scale; *OR*, operating room. (Adapted from Pollack MM, Patel KM, Ruttimann UE: PRISM III: An updated pediatric risk of mortality score. *Crit Care Med* 1996;24:743–52.)

permissive hypercapnia and relative hypoxia in the child with severe respiratory failure; early use of hemofiltration; use of biologic modifying products for sepsis; and high-frequency oscillatory ventilation, with a concomitant decline in the utilization of jet ventilation and ECMO outside the neonatal period. The hope is for increased survival from septic shock, respiratory failure, and ARDS. Performance deemed acceptable against a predictive score standard developed in 1995 may not be reliable, thus necessitating constant reassessment, reevaluation, and updating of pediatric scores. **REFERENCES**

Chapter 57 - Stabilization of the Critically Ill Child

57.1 Pediatric Emergencies and Resuscitation

Lawrence H. Mathers
Lorry R. Frankel

Each year in the United States there are over 150,000 emergencies that threaten the lives of children; approximately 10,000 of these children die, and at least 90,000 survive with permanent disability. These emergencies may need immediate treatment in various settings in the home, community, or hospital. Bystander rescuers, parents, or health care providers may have to provide immediate resuscitation while simultaneously activating the emergency care system and facilitating patient transport to the nearest appropriate facility. The growing number of children with increased vulnerability to serious illness, such as surviving premature infants or children with chronic disease, makes knowledge of how to respond to pediatric emergencies critical (see Chapter 51).

Pediatric emergencies are of various types: respiratory, cardiac, endocrine, traumatic, and infectious. However, most pediatric arrests are respiratory, not cardiac. Sudden, unanticipated, nontraumatic cardiac arrests are uncommon in children in contrast to the primary nature of cardiac arrest in adults from ischemic heart disease and subsequent ventricular fibrillation or ventricular tachycardia. Cardiac arrests in children may develop in the presence of known (preoperative or postoperative congenital heart disease) or unknown (hypertrophic cardiomyopathy, aberrant coronary arteries, prolonged QT syndromes, critical aortic stenosis) lesions during strenuous exercise in adolescents (see Chapter 428.6).

Respiratory arrests are more common in children with pre-existing chronic lung disease or those who become acutely ill with shock or airway compromise (Box 57–1). Respiratory failure is a preterminal event following severe asthma, pneumonia, sudden infant death syndrome (SIDS), submersions, trauma, sepsis, and foreign body or gastric content aspiration.

Cardiopulmonary arrests in a hospital setting are usually initially respiratory arrests and are often predictable. Apnea usually precedes bradycardia with poor perfusion; many patients

Box 57.1-1. Respiratory Emergencies

UPPER AIRWAY OBSTRUCTION

Child usually presents in obvious respiratory distress–with stridor or leaning chin forward and drooling.

Do not put instruments into the airway unless prepared to intubate immediately. This is especially risky in presumed epiglottitis and bacterial tracheitis or foreign body.

Lateral neck radiograph can show enlarged epiglottis at base of tongue or possibly a foreign body.

Major challenge is to avoid irritation of the airway, which can precipitate complete airway obstruction.

SMALL AIRWAYS

Usually this is an exacerbation of a previously existing condition such as asthma, cystic fibrosis, or bronchopulmonary dysplasia. Patients present with wheezing.

Mucus and/or bronchospasm causes air trapping–inspired air more easily enters the alveoli than it leaves them. As a result, the distal airways and alveoli distend with gas and efficient exchange is impaired. Pneumothorax may also occur.

In extreme cases, status asthmaticus or bronchiolitis can be fatal.

Necessary steps for therapy: oxygen, bronchiodilators (aerosols and intravenous), steroids (delayed action), relaxation, and reassurance.

PNEUMONIA

intravenous), steroids (delayed action), relaxation, and reassurance.

PNEUMONIA

Impaired gas exchange is due to alveolar injury; usually involves surfactant deficiency, plus fluid in alveoli.

Therapy: oxygen, antibiotics, mechanical ventilatory support if serious disease.

Parenchymal disease increases the tendency for intrapulmonary shunts, increasing the hypoxia.

Pneumonia becomes life threatening only when large portions of the lungs are involved.

Sickle cell acute chest syndrome is particularly dangerous.

have a pre-existing chronic life-threatening or life-shortening condition. In the hospital, the first recorded electrocardiogram (ECG) is asystole in over 50%; pulseless electrical activity in about 10%; bradycardia with poor perfusion in 25%; and ventricular fibrillation or pulseless ventricular tachycardia in about 15%. The older the patient is, the higher the likelihood of ventricular fibrillation or ventricular tachycardia.

The proper response to each emergency requires an awareness of the mechanisms of disease and the immediate physiologic threats and their proper treatment. A number of factors contribute to the physiologic instability of infants and young children (Box 57–2). Children with recurring life-threatening illnesses (e.g., seizure disorders, asthma, cardiac dysrhythmias) may be able to take precautions to minimize the risk of such threats. Parental vigilance and anticipation of potential dangers in the home, especially for young children, can prevent many injuries and deaths (see Chapter 50).

Emergency personnel should have an approach that will allow them, in the best interest of the patient, to refrain from initiating or terminating resuscitations when efforts are futile. With many chronically ill children being cared for at home or in care facilities, it is not unusual for emergency personnel to be presented with an advanced directive or other document indicating the wish that resuscitation not be performed. It may be difficult to interrupt or not commence a resuscitative effort on the basis of these documents unless a community-wide means of establishing their credibility is developed.

LIFE-THREATENING EMERGENCIES AND PRE-ARREST STATES IN CHILDREN

The most common life-threatening illnesses in children are those involving respiratory (see Chapters 57.3 and 58), cardiac (see Chapters 427–437), or neurologic (see Chapter 57.7) failure. Acute failure of the liver (see Chapter 345), kidneys (see Chapter 527), or adrenals (see Chapter 569) also place pediatric

Box 57.1-2. Factors Contributing to Infant Physiologic Instability

TEMPERATURE

Neonates have thin skin (radiating heat) and underdeveloped hypothalamic control. They lack the efficient neural mechanisms for temperature control (e.g., shivering) and are greatly influenced by environmental temperature.

FLUID REQUIREMENTS

Thin skin allows more evaporation; fluid content in an infant's body is higher than in an adult's (75–80% in newborn); kidneys reabsorb electrolytes inefficiently; infants need proportionately more fluid per unit of weight than adults.

AIRWAY

Airway is small and narrow; resistance to gas flow is inversely proportional to the 4th power of the radius, so small mucous obstructions can seriously threaten air movement; laryngeal and tracheal cartilages are softer than in adults and more easily collapse to obstruct the airway.

CARDIAC OUTPUT

softer than in adults and more easily collapse to obstruct the airway.

CARDIAC OUTPUT

Heart rate is the major mechanism for varying cardiac output.

GLUCOSE METABOLISM

Newborn infants, especially, have only marginal glycogen stores and may mobilize fat poorly; hypoglycemia occurs more readily than in adults, because of dependence on exogenous supply of glucose.

patients at risk. Identifying the cause of various organ failures may take considerable time, but treatment of the physiologically unstable child must begin immediately.

Detecting and Assessing Physiologic Instability.

A simple and consistent approach is necessary for rapid and efficient evaluation of a pediatric patient who may be in serious distress. *Observation* begins with determination of the alertness of the patient, including response to stimuli, spontaneous vocalization or movement, and muscle tone. In basic life support, this is assessed by asking, “Are you all right?” This is followed by assessment of the *vital signs* (Table 57–1) and other basic indicators of the physiologic state.

Pulse and Heart Rate.

The ability to detect a pulse in the compromised patient is unreliable among many lay rescuers. Medical professionals and parents of chronically ill children who were taught to palpate a pulse should do so as part of the initial assessment (Table 57–2). Lay rescuers should check for other physical signs of adequate circulation (breathing, movement, coughing, color) but should not check for a pulse. In children younger than age 8 yr or those with trauma, near-drowning, a drug overdose,

TABLE 57.1-1 -- **Vital Signs at Various Ages**

Age	Heart Rate (beats/min)	Blood Pressure (mm Hg)	Respiratory Rate (breaths/min)
Premature	120–170[*]	55–75/35–45[†]	40–70[‡]
0–3 mo	100–150[*]	65–85/45–55	35–55
3–6 mo	90–120	70–90/50–65	30–45
6–12 mo	80–120	80–100/55–65	25–40
1–3 yr	70–110	90–105/55–70	20–30
3–6 yr	65–110	95–110/60–75	20–25
6–12 yr	60–95	100–120/60–75	14–22
12[*] yr	55–85	110–135/65–85	12–18

** In sleep, infant heart rates may drop significantly lower, but if perfusion is maintained, no intervention is required.*
† A blood pressure cuff should cover approximately two thirds of the arm; too small a cuff yields spuriously high pressure readings, and too large a cuff yields spuriously low pressure readings.
‡ Many premature infants require mechanical ventilatory support, making their spontaneous respiratory rate less relevant.

TABLE 57.1-2 -- **Chest Compression: Ventilation Relationships**

	Neonate	1–8 Yr	> 8 Yr
Compression rate	120	At least 100	100
Compression to ventilation ratio[*]	3:1	5:1	15:2[†]
Pulse check[‡]	Umbilical artery	Brachial	Carotid

** Ventilation should be given without interrupting chest compression. It is asynchronous.*
† Once intubated go to 5:1.
‡ For lay rescuers no pulse check is necessary; it actually delays cardiopulmonary resuscitation. Lay rescuers should check for signs of circulation: cyanosis, breathing, coughing, and movement.

or other obvious respiratory causes of an arrest, the resuscitation should begin before activation of the EMS (the *phone fast protocol*). In children older than age 8 yr or with a history of cardiac disease or with a sudden collapse during exercise, ventricular fibrillation or ventricular tachycardia may be present. This creates a more urgent need to activate EMS to be able to do defibrillation if needed as soon as possible. Therefore, the *phone first protocol* with a lone rescuer involves activating EMS before formal resuscitation. If two rescuers are present, then activation of EMS and resuscitation will be simultaneous. Many community settings (shopping malls, airports, high schools) are equipped with automatic external defibrillators that can be used to rapidly assess the rhythm and to defibrillate (if needed) any child older than 8 yr.

When a child's heart rate lies outside the physiologic parameters, cardiac output may be affected. A rapid heart rate (supraventricular tachycardia or ventricular tachycardia) may be associated with a serious reduction in stroke volume, as reflected in poor perfusion and increased fussiness (see Chapter 428). Cardiac failure may develop with pulmonary edema (see Chapters 57.3 and 394).

Bradycardia also may represent a serious pre-arrest condition (see Chapter 428). Alternatively, the heart rate change may reflect an appropriate physiologic response (sinus tachycardia) and may not necessarily constitute significant cardiac pathophysiology. Sinus tachycardia may be distinguished from supraventricular tachycardia (SVT) by the history as well as the presence of upright P waves in sinus tachycardia in leads I and aVF, whereas SVT may demonstrate negative P waves in leads II, III, and aVF. Sinus tachycardia has a rate that is usually less than 220 beats/min in infants and less than 180 beats/min in children. SVT has an abrupt onset and an abrupt termination and can be terminated by vagal maneuvers (Valsalva, ice water bag to face, or gentle carotid massage), intravenous adenosine, or synchronized cardioversion (0.5–1?J/kg).

Blood Pressure (BP).

This is most often measured by auscultation, but automated devices such as the Dinamap can be set to measure BP repeatedly and at very short intervals (see Chapter 437). To help define poor perfusion, the lower limit of systolic BP should be less than 60?mm?Hg for neonates; less than 70?mm?Hg from 1 mo to 1 yr; less than 70?mm?Hg + 2 × age from 1–10 yr; and less than 90?mm?Hg if older than age 10 yr.

Organ Perfusion.

Adequate cardiac output is reflected in good perfusion of the skin (central and of distal extremities). Skin perfusion may be assessed by the temperature of the skin or by capillary refill time (the time required for color to return to the skin after pressure blanching that part of the skin is released). Normal capillary refill time is 2 seconds or less; however, low environmental temperature may cause peripheral vasoconstriction and lengthening of capillary refill. Pulse oximetry is meant to measure hemoglobin oxygen saturation; because it requires

adequate perfusion to produce reliable measurements, the presence of a strong signal indicates good peripheral perfusion.

Core Temperature.

The normal temperature range for humans is constant throughout life. Premature infants and small term infants may have difficulty maintaining their appropriate core temperature if they are left uncovered in a cool environment. Infants may not be able to generate an elevated temperature in response to infection (see Chapter 98).

Respiratory Effort and Gas Exchange.

Muscle *retractions* in the chest and neck and *flaring* of the nostrils at inspiration are signs of an abnormally high level of effort required to move air into the lungs. *Grunting* is a moaning, crying-like noise at expiration, associated with generation of positive pressure to maintain alveolar patency. A child who is inadequately oxygenated demonstrates *cyanosis* (a blue or dusky color of the skin and mucous membranes) (see Chapters 357 and 359). Although observations of respiratory effort provide useful information about impending respiratory failure, arterial blood gases provide a more accurate assessment of respiratory gas exchange (see Chapters 52 and 359) and evidence of a lactic acidosis due to poor perfusion.

Cardiac Dysrhythmias (see Chapter 428).

Disturbances in cardiac rate and rhythm are not rare in children; the majority of these dysrhythmias are transient and not pathologic. Life-threatening cardiac emergencies in children are more likely to be bradycardia or asystole than ventricular fibrillation, which is more common in adolescents and adults. The prevalence of pediatric rhythm disturbances is rising as more children with congenital heart anomalies undergo surgical correction and survive through childhood. Abnormal cardiac rhythms may be manifested as sudden collapse, dyspnea, tachypnea, tachycardia, palpitations (the consciousness of skipped or irregular beats), syncope, dizziness, or angina (rarely). Tachyarrhythmias or bradycardias may not pose any danger to a patient initially; but when they affect the cardiac output, patients become symptomatic.

The diagnosis and the management of specific rhythm disturbances in children are discussed in Chapter 428 . *Asystole, symptomatic tachycardias*, and *bradycardia* present distinct resuscitative paradigms that require swift recognition and intervention; personnel in offices, clinics, and inpatient areas need to be prepared to manage these complicated situations (Figs. 57–1 (Figure Not Available) to 57–5 (Figure Not Available)). *Electrolyte imbalances* also may produce life-threatening dysrhythmias (see Chapter 45). Children who experience significant fluid

loss or who are receiving diuretics or digoxin are especially at risk.

Alterations of Pulmonary Blood Flow.

In various congenital heart conditions and with some physiologic disturbances, blood flow to the lungs meets with resistance, resulting in pulmonary hypertensive crises. These patients are at risk for serious hypoxic/anoxic events (see Chapter 426).

Assessing Metabolic Status.

Two important acute destabilizing metabolic disorders are acidosis and hypoglycemia. The causes, consequences, and management of respiratory, metabolic, and mixed *acidosis* are discussed in Chapters 45 and 48 . Arterial blood sampling is discussed in Chapter 55 . The measurement of the oxygen content of central venous blood (mixed venous oxygen content [Mv_{O_2}]), especially blood from the pulmonary artery (Swan-Ganz) catheter, is helpful in assessing the adequacy of tissue perfusion and increased anaerobic metabolism. Abnormally low oxygen content of venous blood relative to arterial blood suggests that the delivery of blood to tissues is inadequate, resulting in increased extraction of oxygen and metabolic acidosis. If the venous blood oxygen content is abnormally high, either blood is being delivered too rapidly to the tissues (high cardiac output), so that a lower than normal fraction of oxygen is extracted as blood passes through capillary beds, there is abnormal mixing of venous and arterial blood near the heart and great vessels, or the tissue is no longer viable. Assaying a patient's blood and urine for specific organic acids if

an inborn error is suspected may be helpful in diagnosing an underlying metabolic abnormality.

Current guidelines for resuscitation emphasize establishing airway and ventilation, heart rate, and adequate peripheral perfusion before $NaHCO_3$ or other buffering agent is administered. Sodium bicarbonate is indicated for symptomatic hyperkalemia, hypermagnesemia, some tricyclic antidepressant drug intoxications, or with adverse events due to sodium channel blocking agents. Routine administration during CPR is discouraged because it may be dangerous. Sodium bicarbonate use should be considered in the presence of a severe metabolic acidosis as documented by arterial blood gas analysis and during a prolonged resuscitation when it may be given every 10?min during the arrest.

Hypoglycemia is defined as low blood glucose level that destabilizes energy production (see Chapters 81 and 96.2). The brain is dependent on an adequate level of circulating glucose and requires a constant supply to support energy-consuming cerebral activities. Hypoglycemia produces weakness and lethargy and can lead to seizures and coma. Emergency resuscitation should usually include intravenous administration of glucose (250–500?mg/kg, infused over 1–2?min; hypoglycemia should be documented if this does not delay treatment).

Assessing Central Nervous System Function.

The integrity of the CNS is assessed by the history and physical examination, which should determine the possibility of trauma, toxic and/or drug ingestions, seizures, ischemia, and signs of any expanding intracranial lesion (hemorrhage, tumor, abscess, vascular malformation). Tables 57–3 and 57–4 are examples of important

Clinical Stage				
1	***2***	***3***	***4***	***5***
Lethargic	Combative	Comatose	Comatose	Comatose
Follows commands	Inconsistent following of commands	Occasional response to commands	Responds only to pain	No response to pain
Pupils reactive	Pupils sluggish	Eyes may deviate	Weak pupillary response	No pupillary response
Breathing normal	May hyperventilate	Irregular breathing	Very irregular breathing	Requires mechanical ventilation
Normal muscle tone	Reflexes inconsistent	Decorticate posturing	Decerebrate posturing	Absent tendon reflexes—flaccid

scoring or staging criteria universally used to assess neurologic status. These scales should be scored serially over time to detect disease improvement or progression.

Glasgow Coma Scale (GCS).

Although this scale has not been validated as a prognostic scoring system for infants and young children as it has been in adults, the GCS is commonly used in assessment of pediatric patients with an altered level of consciousness, especially those who have sustained a traumatic head injury (see Table 57–3). The GCS provides very rapid assessment of cerebral cortical function. Patients with a GCS score of 8 or less may require aggressive management, including mechanical ventilation and intracranial pressure monitoring.

RESUSCITATION

The goal in pediatric resuscitation is to maintain adequate oxygenation and perfusion of blood throughout the body while steps are taken to stabilize a child and establish long-term homeostasis. An orderly sequence of events should be instituted, beginning with the ABCs: airway, breathing, and circulation. (See Chapter 51 and Fig. 57–1 (Figure Not Available) .) In addition to airway, “A” also represents assessment of responsiveness (“Are you all right?”), activation of the EMS, and anticipation of high-risk situations such as trauma, respiratory distress, or exacerbations of chronic life-shortening conditions. Anticipation is a key to the prevention of cardiopulmonary arrests.

Many pediatric patients undergoing resuscitation recover to a substantial degree. Hospitalized children with acute life-threatening conditions often recover spontaneous circulation after an arrest. Children with a respiratory arrest, a short duration of CPR, and a pulse present at the time of apnea have the best chance of survival. The majority of survivors have no change in their neurologic function compared with their pre-arrest status. If a patient is asystolic on arrival at the hospital or in the advanced stages of a chronic disease process before receiving acute medical care, the chances for a successful resuscitation decline dramatically.

Respiratory Support.

If no obstruction by a foreign body is found and if a child has no spontaneous respirations, steps should be immediately taken to breathe for the child. A common cause of airway obstruction in an unresponsive child is the tongue occluding the airway. Assessment includes opening the airway (head tilt/chin lift or jaw thrust if the cervical spine is unstable) and looking for the rise and fall of the chest as well as a foreign body, listening at the nose and mouth for breathing, and feeling air exiting the child's airways (Figs. 57–6 and 57–7). This should be done in less than 10 seconds. If a foreign body is seen, it should be removed; health care workers should perform a tongue/jaw lift if a foreign body is suspected but not initially visualized. If the patient resumes adequate spontaneous ventilation, the patient's body is turned on its side to the recovery position with the head to the side (if in the field).

Rescue breathing should be done by *mouth-to-mouth* or *mouth-to-nose* breathing, a mask over the patient's nose and mouth and *mouth-to-mask* breathing, or *bag-mask* respirations (Figs. 57–8

Figure 57.1-6 Opening the airway with the head tilt-chin lift maneuver. One hand is used to tilt the head, extending the neck. The index finger of the rescuer's other hand lifts the mandible outward by lifting on the chin. Head tilt should not be performed if cervical spine injury is suspected. (From Emergency Cardiac Care Committee and Subcommittees, American Heart Association: Pediatric basic life support, part 5. *JAMA* 1992;268:2251.)

and 57–9). Successful rescue breathing will provide good chest rise and relief of deep cyanosis. Exhaled air is 16–17% oxygen, which corresponds to an alveolar oxygen pressure of 80?mm?Hg in the patient. If these measures do not facilitate adequate air

Figure 57.1-7 Combined jaw thrust-spine stabilization maneuver for the pediatric trauma victim. (From Emergency Cardiac Care Committee and Subcommittees, American Heart Association: Pediatric basic life support, part 5. *JAMA* 1992; 268:2251.)

Figure 57.1-8 Rescue breathing in an infant. The rescuer's mouth covers the infant's nose and mouth, creating a seal. One hand performs head tilt while the other hand lifts the infant's jaw. Avoid head tilt if the infant has sustained head or neck trauma. (From Emergency Cardiac Care Committee and Subcommittees, American Heart Association: Pediatric basic life support, part 5. *JAMA* 1992;268:2251.)

entry, recheck that the airway is patent and the seal is tight; if so endotracheal intubation is indicated. Indicators for endotracheal intubation include apnea, loss of CNS control of respirations, airway obstruction unrelieved by airway opening maneuvers, increased work of breathing that may lead to fatigue, the need for positive end-expiratory pressure (PEEP) or

Figure 57.1-9 Rescue breathing in a child. The rescuer's mouth covers the mouth of the child, creating a mouth-to-mouth seal. One hand maintains the head tilt; the thumb and forefinger of the same hand are used to pinch the child's nose. (From Emergency Cardiac Care Committee and Subcommittees, American Heart Association: Pediatric basic life support, part 5. *JAMA* 1992;268:2251.)

a high peak inspiratory pressure (PIP), poor airway protective reflexes, sedation, or the need for paralysis. Once the patient is intubated, proper tube placement is assessed by breath sounds, chest rise, and instantaneous analysis of exhaled carbon dioxide (CO_2) by a colorimetric device placed within the respiratory tubing near the endotracheal tube (ETT). Confirmation of ETT position by exhaled CO_2 is most reliable with a perfusing rhythm. A simple formula for selecting the appropriate size ETT is as follows:

The respiratory rate parameters that should be maintained are indicated in Table 57–2 .

In the field, competent bag-mask ventilation may be preferable to repeated attempts at endotracheal intubation by inadequately experienced personnel. The airway in children differs from that of the adult because it is smaller, more anteriorly placed, more difficult to visualize, and more prone to mucosal injuries leading to subglottic stenosis.

Foreign body aspiration always should be suspected if respiratory distress has had a sudden onset (see Chapter 372) or if the chest does not rise when ventilation is first attempted in an unconscious, apneic infant or child. A conscious child suspected of a foreign body partial obstruction should be permitted to cough spontaneously until coughing is not effective (or aphonic), respiratory distress and stridor increase, or the child becomes unconscious. The airway is then opened with the head-tilt/chin-lift maneuver, and ventilation is attempted. If unsuccessful, the airway is repositioned and ventilation again attempted. If there is still no chest rise, attempts to remove a foreign body are indicated. In the infant younger than 1 yr, a combination

Figure 57.1-10 Back blows (top) and chest thrusts (bottom) to relieve foreign-body airway obstruction in the infant. (From Emergency Cardiac Care Committee and Subcommittees, American Heart Association. Pediatric basic life support, part 5. *JAMA* 1992;268:2251.)

of five back blows and five chest thrusts are administered (Fig. 57–10). The foreign body is removed if it is seen. If no foreign body is visualized, ventilation is again attempted. If this is unsuccessful, the head is repositioned and ventilation attempted again. If there is no chest rise, the series of back blows and chest thrusts are repeated.

A conscious child older than 1 yr is administered a series of five abdominal thrusts (the Heimlich maneuver) with the child standing or sitting (Fig. 57–11). If unconscious, this is done with the child lying down (Fig. 57–12). After the abdominal thrusts, the airway is examined for a foreign body, which should be removed if visualized. If no foreign body is seen, the head is repositioned and ventilation attempted. If unsuccessful, repositioning the head and attempted ventilation are repeated. If unsuccessful, the Heimlich sequence is repeated.

Cardiovascular Support.

As resuscitation proceeds and ventilation is started, support of the *circulation* should be provided to sustain adequate blood flow to deliver oxygen to the tissues (Figs. 57–13 , 57–14 , and 57–15). Circulation is assessed by lay rescuers without checking for a pulse, while health care workers or trained parents should check for a pulse (see Table 57–2). If there is no pulse or if the pulse is less than 60 beats/min with poor perfusion, chest compressions must be given. Chest compressions are given without interrupting ventilations. The effectiveness of chest compressions is determined by the presence of a palpable pulse. The rate of chest compressions varies with age and size (see Table 57–2). Chest compressions in small infants and newborns may be performed by placing two thumbs on the midsternum with the hands encircling the thorax, or by two fingers over the midsternum and compressing, or by holding the child in the supine posture on one's lap. When feasible, a cardiac resuscitation board should be placed under the child's back to maximize efficiency of compressions. The resuscitation effort should pause

Figure 57.1-11 Abdominal thrusts with victim standing or sitting (conscious). (From Emergency Cardiac Care Committee and Subcommittees, American Heart Association: Pediatric basic life support, part 5. *JAMA* 1992;268:2251.)

Figure 57.1-14 Locating hand position for chest compression in a child. Note that the rescuer's other hand is used to maintain head position to facilitate ventilation. (From Emergency Cardiac Care Committee and Subcommittees, American Heart Association: Pediatric basic life support, part 5. *JAMA* 1992;268: 2251.)

periodically to make an assessment of the possible return of spontaneous heart rate, pulse, and respirations. If the resuscitative efforts do not succeed in re-establishing respiration and heartbeat, the medical team must decide whether continued efforts are warranted or if the resuscitation should be stopped. If resuscitation is to continue and spontaneous heart rate and respirations have not returned, then the patient should be intubated, vascular access established, and administration of resuscitative drugs initiated. In the field with a pulseless child, an automatic external defibrillator may be available and should be used in children older than 8 yr of age if ventricular fibrillation is present.

Intubation and Mechanical Ventilation.

Although it is possible to intubate awake infants without sedation, analgesia, or paralysis,

Figure 57.1-15 Two thumb-encircling hands chest compression technique in infant (2 rescuers). (From Emergency Cardiac Care Committee and Subcommittees, American Heart Association: Pediatric basic life support, part 9. *Circulation* 2000;102:1–253.)

analgesia is recommended to reduce metabolic stress (see Chapter 65). Children 1 mo of age or older should be pretreated with a sedative, an analgesic, and possibly a muscle relaxant unless the situation is an emergency (apnea, asystole, unresponsiveness) and the administration of drugs would cause an unacceptable delay. The intubation technique is shown in Figure 57–16 .

Figure 57.1-16 Intubation technique. (From Fleisher G, Ludwig S: *Textbook of Pediatric Emergency Medicine*. Baltimore, Williams & Wilkins, 1983, p 1250.)

In a *controlled intubation*, patients should fast for at least 4?hr or have their stomach emptied by nasogastric tube. The history and physical examination should be reviewed for any allergies or evidence of unusual airway anatomy, or risk for malignant hyperthermia, and informed consent should be obtained. Equipment necessary for intubation and bag-mask ventilation and an emergency cricothyrotomy tray should be available.

After a period of hyperoxygenation, a benzodiazepine (diazepam, midazolam, lorazepam) should be administered, followed by an opiate (fentanyl, remifentanil, morphine), and a paralytic agent (vecuronium, rocuronium).

Because many intubations in critically ill children are emergent, the foregoing steps often cannot be followed, and procedures for *rapid sequence intubation* (RSI) should be initiated (Table 57–5). The goals of RSI are to induce anesthesia and paralysis and complete intubation rapidly. This minimizes elevations of intracranial and blood pressure that may accompany intubation in awake or lightly sedated patients. Because the stomach generally cannot be emptied before RSI, the **Sellick maneuver** (compression of the cricoid cartilage backward, compressing the esophagus against the vertebral column) should be used to prevent aspiration of gastric contents, which is very likely to occur when the laryngoscope and ETT are inserted into the pharynx and larynx.

Under controlled circumstances, *nasotracheal intubation* may be performed. It is indicated in patients who are going to be lightly sedated or when there is significant oral trauma. A nasotracheal tube causes less noxious sensations than does an *orotracheal tube*, which passes across the tongue and gums, producing a gag reflex in the posterior pharynx. Nasotracheal tubes do, however, obstruct sinus and eustachian tube drainage, and sinus or middle ear infections may result.

Cricothyrotomy.

When the airway is obstructed and tracheal intubation has not succeeded, *needle cricothyrotomy* is indicated. The patient should be supine with the face looking directly upward. The midpoint of the cricothyroid membrane is palpated, and a 14-gauge intravenous catheter with stylet is advanced slowly through it, inclined inferiorly at about 45 degrees. Quick aspiration of air through a syringe connected to the catheter indicates entry into the trachea. At this point, the metal stylet is removed and the catheter is pushed farther downward into the trachea. Oxygen should be flushed through the catheter at 10–15?L/min. This supports a child, even one with little or no spontaneous respirations, while plans for a more secure airway are made. *Surgical cricothyrotomy* is rarely necessary in children and should be performed by an experienced surgeon, except in severe

TABLE 57.1-5 -- Rapid Sequence Intubation

Step	Procedure	Comment/Explanation
1	Brief history and assessment	R/O drug allergies; examine airway anatomy (e.g., micrognathia, cleft palate).
2	Assemble equipment, medications, etc.	See lists below.
3	Preoxygenate patient	With bag/mask, nasal cannula, hood or “blow-by.”
4	Premedicate with lidocaine, atropine	Lidocaine minimizes intracranial pressure rise with intubation and can be applied topically to airway mucosa for local anesthesia.

		Atropine helps blunt the bradycardia associated with upper airway manipulation and reduces airway secretions.
5	Sedation and analgesia induced	Sedatives: *Thiopental* (2–5?mg/kg)—very rapid onset; can cause hypotension. *Diazepam* (0.1?mg/kg)—onset 2–5?min; elimination 30–60?min or more. *Ketamine* (2?mg/kg)—onset 1–2?min, elimination in 30–40?min. May cause hallucinations if used alone; causes higher ICP, mucous secretions, increased vital signs, and bronchodilation. Analgesics: *Fentanyl:* 3–10?µ/kg, may repeat 3–4×. Rapid administration risks “tight chest” response, with no effective ventilation. Effects wear off in 20–30?min. *Morphine:* 0.05–0.1?mg/kg/dose; may last 30–60?min, may lead to hypotension in hypovolemic patients.
6	Pretreat with nondepolarizing paralytic agent	Small dose of nondepolarizing paralytic agent (see below), with intent of diminishing the depolarizing effect of succinylcholine, which is administered next.
7	Administer muscle relaxants	Succinylcholine dose is 1–2?mg/kg; causes initial contraction of muscles, then relaxation. This depolarization can, however, raise ICP and blood pressure. Onset of paralysis in 30–40?sec; duration 5–10?min.
		Increased use of pretreatment with a nondepolarizing muscle relaxant, especially rocuronium (1?mg/kg), which has a very quick onset and short duration. Other nondepolarizing agents include vecuronium and pancuronium, both dosed at 0.1?mg/kg.
8	Sellick maneuver	Pressure on cricoid cartilage, to occlude esophagus and prevent regurgitation or aspiration.
9	Endotracheal intubation	Endotracheal tubes: select proper size for age and weight of child.
		Laryngoscope blades: variety of Miller and Macintosh blades.
		Patient supine: neck extended moderately to "sniffing" position.
10	Secure tube, verify position with roentgenogram	ET tube secured with tape to cheeks and upper lip or to an adhesive patch applied to the skin near the mouth.
11	Begin mechanical ventilation	Verify tube placement before ventilating with positive pressure; if ET in one bronchus, barotrauma may occur.

ICP = intracranial pressure; ET = endotracheal.

emergencies. It involves making a transverse incision in the cricothyroid membrane and advancing a large catheter through the incision downward into the lower trachea. Although similar in principle to a needle cricothyrotomy, the risk of bleeding, upper airway obstruction, and pneumothorax are significantly greater.

Venous Access.

Veins suitable for cannulation are numerous, but there is considerable anatomic variation. The *dorsum of the foot* usually has a large vein in the midline, passing across the ankle joint, but a catheter is difficult to maintain in this vein because dorsiflexion tends to dislodge it. A second large vein on the *lateral side of the foot*, running in the horizontal plane, usually 1–2?cm dorsal to the lower margin of the foot, is preferable (Fig. 57–17 (Figure Not Available)). The great saphenous vein is accessible in all patients. It is cannulated just anterior to the medial malleolus and may be accessible in the medial leg and thigh in premature infants.

Of the numerous veins on the *dorsum of the hand*, many are suitable for cannulation. The vessels are large and often secured on the flat surface of the dorsum of the hand, and cannulation is well tolerated. There is almost always a large vein lying in the interspace of the 4th and 5th digits, about 1?cm proximal to the metacarpophalangeal joints. The *cephalic vein* is usually cannulated at the wrist, along the forearm, or at the elbow (Fig. 57–18 (Figure Not Available)). The *median vein of the forearm* is also suitable because it lies along a flat surface of the forearm. The *basilic vein* is prone to sliding around when attempts are made to cannulate it.

Samples of blood may be obtained from the external and internal *jugular veins* or, in neonates, from various *scalp veins*. The two jugular veins are also potential sites for indwelling catheters (Fig. 57–19 (Figure Not Available)). The most notable scalp veins are the superficial temporal (just anterior to the ear) and posterior auricular (just behind the ear).

Deeper and larger veins are very valuable because they provide a reliable access for medications, nutritive solutions, and blood sampling. They may be reached by percutaneous cannulation or by surgical exposure. To cannulate the *femoral vein*, after the skin is cleaned, a needle is inserted about 0.5?cm medial to the pulsing femoral artery (or, if no pulse, about two thirds of the way from the anterior-superior spine to the pubic tubercle

Figure 57.1-17 (Figure Not Available) Veins of the lower extremity. (From American Heart Association: *A Textbook of Pediatric Advanced Life Support*. Dallas, American Heart Association, 1994, with permission. © 1994, American Heart Association.)

(Fig. 57–20 (Figure Not Available)). Slight backward pressure on the plunger of a connected syringe is maintained so that blood flows easily into the syringe once the vessel is punctured. After the vessel is located, a small wire is advanced through the needle into the lumen of the vessel. The needle is then removed and the catheter is threaded over the wire into the vessel **(Seldinger technique)**. In small infants, the vein is no more than 0.5–1?cm below the surface, so the needle puncture should be

at a shallow angle. In large

Figure 57.1-18 (Figure Not Available) Veins of the upper extremity. (From American Heart Association: *A Textbook of Pediatric Advanced Life Support*. Dallas, American Heart Association, 1994, with permission. © 1994, American Heart Association.

Figure 57.1-19 (Figure Not Available) The internal and external jugular veins. RMV = retromandibular vein; FV = facial vein; ST = superior thyroid vein; IJ = internal jugular vein; EJ = external jugular vein; SCM = sternocleidomastoid muscle. The two heads of the SCM are indicated by the leader lines connecting that word to the diagram. (From Mathers LW, Smim DW, Frankel L: Anatomic considerations in placement of central venous catheters. *Clin Anat* 1992;5:89. Reprinted by permission of Wiley-Liss.)

adolescents or very obese patients, the needle may need to be nearly perpendicular to the skin. In either case, once the vein is entered, the needle should be flattened out before advancing it farther into the vein. Similar but distinctive cannulation techniques are used in providing access to the subclavian vein and the internal jugular vein. They involve the risk of pneumothorax in addition to bleeding. Because of its proximity to the median nerve the brachial vein is not often recommended for cannulation.

Current recommendations urge the use of intraosseous cannulation in those patients for whom intravenous access is difficult or unattainable, even in older children. If venous access is not available in an arrest situation within 1?min, an intraosseous line should be placed in the anterior tibia. A wide variety of laboratory tests can be performed and many medications and fluids may be administered through this route, including most involved in emergency resuscitations. Administration of certain drugs is also possible through the ETT. Drugs effective through this route include lidocaine, atropine, naloxone, and epinephrine. Epinephrine should be given at 10 times the intravenous dose.

DRUG THERAPY AND DEFIBRILLATION

If ventilation and chest compressions do not restore the circulation and spontaneous respirations, medications may be needed. If there is ECG evidence of a potentially perfusing rhythm but no pulse is palpated, one should consider the causes of pulseless electrical activity (electrical-mechanical dissociation). These include hypothermia, hypoxia, hypovolemia, hyperkalemia, tension pneumothorax, pericardial tamponade, toxins, and pulmonary thromboembolism (Table 57–6).

If there is bradycardia, asystole, ventricular tachycardia, or ventricular fibrillation, the patient requires drug therapy and, when indicated, defibrillation (Table 57–7 ; see Figs. 57–1 (Figure Not Available) , 57–2 (Figure Not Available) , 57–3 (Figure Not Available) , 57–4 (Figure Not Available) , and 57–5 (Figure Not Available)). Epinephrine should initially be used in the standard dose (0.01?mg/kg, which is 0.1?mL/kg of 1:10,000 solution). If the
